Abstract

We introduce a weight update formula that is expressed only in terms of firing rates and their derivatives and that results in changes consistent with those associated with spike-timing dependent plasticity (STDP) rules and biological observations, even though the explicit timing of spikes is not needed. The new rule changes a synaptic weight in proportion to the product of the presynaptic firing rate and the temporal rate of change of activity on the postsynaptic side. These quantities are interesting for studying theoretical explanation for synaptic changes from a machine learning perspective. In particular, if neural dynamics moved neural activity towards reducing some objective function, then this STDP rule would correspond to stochastic gradient descent on that objective function.

1 Introduction

Biological experiments (Markram and Sakmann, 1995; Gerstner *et al.*, 1996) suggest that synaptic change in several types of neurons and stimulation contexts depends on the relative timing of presynaptic and postsynaptic spikes. Learning rules that mimic this observation are called Spike-Timing Dependent Plasticity (STDP) rules. In this paper, we investigate a learning rule that only depends on firing rates and their temporal derivative while being consistent with the STDP observations, according to a series of simulations.

This learning rule is motivated by the desire to make it easier to study machine learning interpretations for STDP, since artificial neural networks are generally cast in terms of firing rates. Deep neural networks (Goodfellow *et al.*, 2015) have been extremely successful in several major artificial intelligence applications in areas such as computer vision, speech recognition, natural language processing, game playing and robotics. All of these breakthroughs have been achieved thanks to at least two ingredients: (a) a deep enough neural

network (with enough layers) and (b) a form of stochastic gradient descent on an objective function of interest, where the gradient is obtained by back-propagation (Rumelhart *et al.*, 1986).

To illustrate the potential use of the proposed STDP rule in bridging the gap between machine learning based back-propagation and biology, we show that this STDP rule would correspond to stochastic gradient descent on an objective function if the neural activity would move towards reducing that objective function.

As usual, we assume the existence of a non-linear transformation ρ that is monotonically increasing, from the integrated activity (the expected membrane potential, averaged over the random effects of both pre- and postsynaptic spikes) to the actual firing rate. In deriving a link between STDP and their rate-based learning rule Xie and Seung (2000) started by assuming a particular pattern relating spike timing and weight change, and then showed that the resulting weight change could be approximated by the product of presynaptic firing rate and temporal rate of postsynaptic firing rate. Instead, we go in the other direction, showing that if the weight change is proportional to the product of presynaptic firing rate (or simply the presence of a spike) and the postsynaptic activity, then we recover a relationship between spike timing and weight change that has the precise characteristics of the one observed experimentally by biologists. We present both an easy to understand theoretical justification for this result, as well as, simulations that confirm it.

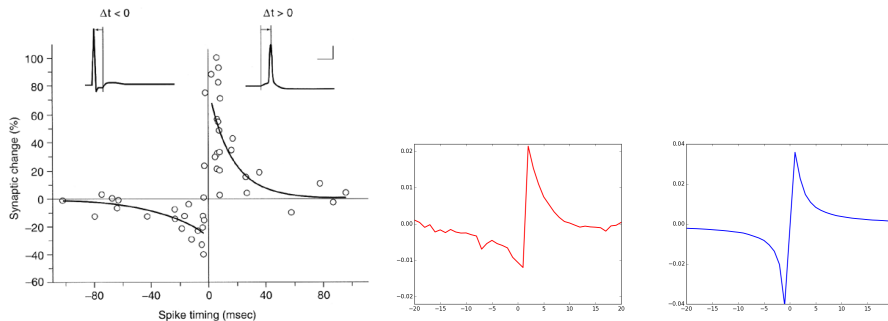

Figure 1: Left: Biological observation of STDP weight change, vertical axis, for different spike timing differences (post minus pre), horizontal axis. From Shepherd (2003), with data from Bi and Poo (2001). Compare with the result of the simulations using the objective function proposed here (middle).

Middle and right: Spike-based simulation shows that when weight updates follow SGD on the proposed predictive objective function, we recover the biologically observed relationship between spike timing difference (horizontal axis, postsynaptic spike time minus presynaptic spike time) and the weight update (vertical axis). Middle: the weight updates are obtained with the proposed update rule (Eq. 1). Right: the weight updates are obtained using the nearest neighbor STDP rule. Compare with the biological finding, left.

2 Spike-timing dependent plasticity

Spike-timing dependent plasticity (STDP) is a central subject of research in synaptic plasticity but much more research is needed to solidify the links between STDP and a machine learning interpretation of it at the scale of a whole network, i.e., with “hidden layers” which need to receive a useful training signal. See Markram *et al.* (2012) for a recent review of the neuroscience research on STDP.

We present here a simple view of STDP that has been observed at least in some common neuron types and preparations. There is a weight change if there is a presynaptic spike in the temporal vicinity of a postsynaptic spike: that change is positive if the postsynaptic spike happens just after the presynaptic spike (and larger if the timing difference is small), negative if it happens just before (and again, larger if the timing difference is small, on the order of a few milliseconds), as illustrated with the biological data shown in Figure 1 (left) from Bi and Poo (2001). The amount of change decays to zero as the temporal difference between the two spikes increases beyond a few tens of milliseconds. We are thus interested in this temporal window around a presynaptic spike during which a postsynaptic neuron spikes, before or after the presynaptic spike, and this induces a change of the weight.

Keep in mind that the above pattern of spike-timing dependence is only one aspect of synaptic plasticity. See Feldman (2012) for an overview of aspects of synaptic plasticity that go beyond spike timing, including firing rate (as one would expect from this work) but also synaptic cooperativity (nearby synapses on the same dendritic subtree) and depolarization (due to multiple consecutive pairings or spatial integration across nearby locations on the dendrite, as well as the effect of the synapse’s distance to the soma).

2.1 Rate-based aspect of STDP

Let s_i represent an abstract variable characterizing the integrated activity of neuron i , with \dot{s}_i being its temporal rate of change. To give a precise meaning to s_i , we define $\rho(s_i)$ as being the firing rate of neuron i , where ρ is a bounded non-linear activation function that converts the integrated voltage potential into a probability of firing.

A hypothesis inspired by Xie and Seung (2000) and Hinton (2007) is that the STDP weight change can be associated with the temporal rate of change of postsynaptic activity, as a proxy for its association with post minus presynaptic spike times. Both of the above contributions focus on the rate aspect of neural activity, and this is also the case of this paper.

Using the notation introduced above, the proposed equation for the average weight change for the synapse associated with presynaptic neuron i and postsynaptic neuron j is the following:

$$\Delta W_{i,j} \propto \dot{s}_i \rho(s_j) . \tag{1}$$

Since stochastic gradient only cares about the *average change*, we could as well have written

$$\Delta W_{i,j} \propto \dot{s}_i \xi_j, \quad (2)$$

where ξ_j is the binary indicator of a spike from neuron j . This works if we assume that the input spikes are randomly drawn from a Poisson process with a rate proportional to $\rho(s_j)$, i.e., we ignore spike synchrony effects (which we will do in the rest of this paper, and leave for future work to investigate). Note that in our simulations, we approximated the Poisson process by performing a discrete-time simulation with a binomial draw of the binary decision spike versus no spike within the time interval of interest.

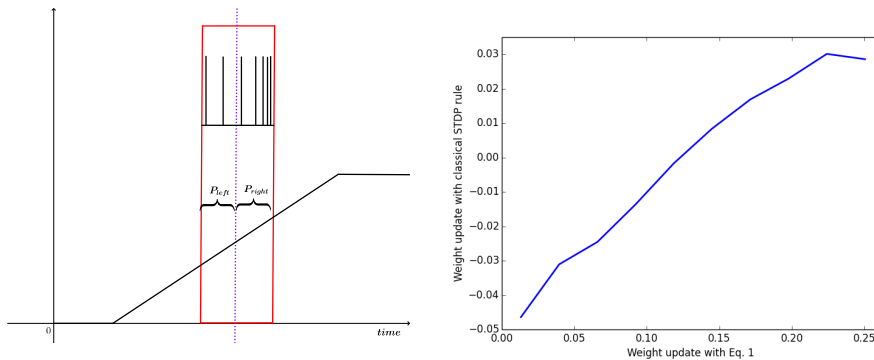

Figure 2: Left: When the postsynaptic rate (y-axis) is rising in time (x-axis), consider a presynaptic spike (middle dotted vertical line) and a window of sensitivity before and after (bold red window). Because the firing probability is greater on the right sub-window, one is more likely to find a spike there than in the left sub-window, and it is more likely to be close to the presynaptic spike if that slope is higher, given that when spikes occur on both sides, no weight update occurs. This induces the appropriate correlation between spike timing and the temporal slope of the postsynaptic activity level, which is confirmed by the simulation results of Section 3 and the results on the right.

Right: The average STDP update according to the STDP nearest neighbor rule (vertical axis) versus the weight update according to the proposed rule (Eq. 1) (horizontal axis). We see that in average over samples (by binning values of the x-axis values), the two rules agree closely, in agreement with the visual inspection of Fig. 1.

2.2 Why it works

Consider a rising postsynaptic activity level, i.e., $\dot{s}_i > 0$, as in Figure 2 (left) and a presynaptic spike occurring somewhere during that rise. We assume a Poisson process for the postsynaptic spike as well, with a rate proportional to

$\rho(s_i)$. According to this assumption, postsynaptic spikes are more likely in a fixed time window following the presynaptic spike than in a window of the same length preceding it. Therefore, if only one spike happens over the window, it is more likely to be after the presynaptic spike, yielding a positive spike timing difference, at the same time as a positive weight change. The situation would be symmetrically reversed if the activity level was decreasing, i.e., $\dot{s}_i < 0$ and negative spike times are more likely.

Furthermore, the stronger the slope \dot{s}_i , the greater will this effect be, also reducing the relative spike timing between the presynaptic spike and stochastically occurring postsynaptic spikes, possibly just after or just before the presynaptic spike. This assumes that when spikes occur on both sides and with about the same time difference, the effects on $W_{i,j}$ cancel each other. Of course, the above reasoning runs directly in reverse when the slope of s_i is negative, and one gets negative updates, in average. To validate these hypothesis, we ran the simulations presented in Section 3. They confirm these hypotheses and show that Eq. 1 yields a relationship between spike timing difference and weight change that is consistent with biological observations (Fig. 1).

3 Simulation results

3.1 Method

We simulate random variations in a presynaptic neural firing rate $\rho(s_j)$ as well as random variations in the postsynaptic firing rates $\rho(s_i)$ induced by an externally driven voltage. By exploring many configurations of variations and levels at pre- and postsynaptic sides, we hope to cover the possible natural variations. We generate and record pre- and postsynaptic spikes sampled according to a binomial at each discrete t with probability proportional to $\rho(s_i)$ and $\rho(s_j)$ respectively, and record \dot{s}_i as well, in order to implement either a classical nearest neighbor STDP update rule or Eq. 1,¹ The nearest neighbor STDP rule is as follows. For every presynaptic spike, we consider a window of 20 time steps before and after. If there is one or more postsynaptic spike in both left and right windows, or no postsynaptic spike at all, the weight is not updated. Otherwise, we measure the time difference between the closest postsynaptic spike (nearest neighbor) and the presynaptic spike and compute the weight change using the current variable values. If both spikes coincide, we make no weight change. To compute the appropriate averages, 500 random sequences of rates are generated, each of length 160 time steps, and 1000 randomly sampled spike trains are generated according to these rates.

For measuring the effect of weight changes, we measure the average squared rate of change $E[|\dot{s}_i^2|]$ in two conditions: with weight changes (according to Eq. 1), and without.

¹ Python scripts for those simulations are available at http://www.iro.umontreal.ca/~bengioly/src/STDP_simulations.

3.2 Results

Examples of the spike sequences and underlying pre- and postsynaptic states s_i and s_j are illustrated in Fig. 3.

Figure 3: Example of rate and spike sequence generated in the simulations, along with weight changes according to the spike-dependent variant of our update rule, Eq. 2. Top: presynaptic spikes ξ_j (which is when a weight change can occur). Middle: integrated postsynaptic activity s_j . Bottom: value of the updated weight $W_{i,j}$.

Fig. 1 (middle and right) shows the results of these simulations, comparing the weight change obtained at various spike timing differences for Eq. 1 and for the nearest neighbor STDP rule, both matching well the biological data (Fig. 1, left). Fig. 2 shows that both update rules are strongly correlated, in the sense that for a given amount of weight change induced by one, we observe in average a linearly proportional weight change by the other.

3.3 Link to Stochastic Gradient Descent and Back-Propagation

Let us consider the common simplification in which postsynaptic neural activity s_i is obtained as a sum with the usual terms proportional to the product of synaptic weight ($W_{i,j}$) and presynaptic firing rate ($\rho(s_j(t-1))$), i.e., in discrete time,

$$s_i(t) = \alpha + \beta \sum_j W_{i,j} \rho(s_j(t-1)).$$

from some quantities α and β . In that case,

$$\frac{\partial s_i(t)}{\partial W_{i,j}} = \beta \rho(s_j(t-1)).$$

Stochastic gradient descent on W with respect to an objective function J would follow

$$\begin{aligned}\Delta W_{i,j} &\propto \frac{\partial J}{\partial W_{i,j}} = \frac{\partial J}{\partial s_i(t)} \frac{\partial s_i(t)}{\partial W_{i,j}} \\ &= \frac{\partial J}{\partial s_i(t)} \rho(s_j(t-1)).\end{aligned}\tag{3}$$

Hence, if

$$\frac{\partial J}{\partial s_i(t)} \propto \dot{s}_i(t),\tag{4}$$

our STDP rule (Eq. 1) would produce stochastic gradient on J .

The assumption in Eq. 4 and the above consequence was first suggested by Hinton (2007): neurons would change their average firing rate so as make the network as a whole produce configurations corresponding to better values of our objective function. This would make STDP do gradient descent on the prediction errors made by the network.

But how could neural dynamics have that property? That question is not completely answered, but as shown in Bengio and Fischer (2015), a network with symmetric feedback weights would have the property that a small perturbation of “output units” towards better predictions would propagate to internal layers such that hidden units s_i would move to approximately follow the gradient of the prediction error J with respect to s_i , making our STDP rule correspond approximately to gradient descent on the prediction error. The experiments reported by Scellier and Bengio (2016) have actually shown that these approximations work and enable a supervised multi-layer neural network to be trained.

4 Related work

The closest work to this paper is probably that of Xie and Seung (2000), which we have already discussed. Notable additions to this work include demonstrating that the spike-timing to weight change relationship is a *consequence* of Eq. 1, rather than the other way around (and a small difference in the use of ds/dt versus $d\rho(s)/dt$).

There are of course many other papers on theoretical interpretations of STDP, and the reader can find many references in Markram *et al.* (2012), but more work is needed to explore the connection of STDP to machine learning. Many approaches (Fiete and Seung, 2006; Rezende and Gerstner, 2014) that propose how hidden layers of biological neurons could get credit assignment rely on variants of the REINFORCE algorithm (Williams, 1992) to estimate the gradient of a global objective function (basically by correlating stochastic variations at each neuron with the changes in the global objective). Although this principle is simple, it is not clear that it will scale to very large networks due to the linear growth of the variance of the estimator with the number of neurons. It is therefore tempting to explore other avenues.

The proposed rule can be contrasted with theoretical synaptic learning rules which tend to be based on the Hebbian product of pre- and postsynaptic activity, such as the BCM rule (Bienenstock *et al.*, 1982; Intrator and Cooper, 1992). The main difference is that the rule studied here involves the temporal derivative of the postsynaptic activity, rather than the actual level of postsynaptic activity.

5 Conclusion and Open Questions

We have shown through simulations and a qualitative argument that updating weights in proportion to the rate of change of postsynaptic activity times the presynaptic activity yielded behavior similar to the STDP observations, in terms of spike timing differences.

This is consistent with a view introduced by Hinton (2007) that neurons move towards minimizing some prediction error because it would make this STDP rule perform stochastic gradient descent on that prediction error. In parallel to this work, Bengio and Fischer (2015) has shown how early propagation of perturbations in a recurrent network behaves like gradient propagation in a layered network, and could compute the gradients necessary for learning using our proposed STDP update. Scellier and Bengio (2016) have actually shown through experiments using this approach that it was possible to train deep supervised neural networks.

Many open questions also remain on the side of biological plausibility. STDP only describes one view of synaptic plasticity, and it may be different in different neurons and preparation. A particularly interesting type of result to consider in the future regards the relationship between more than two spikes induced statistically by the proposed STDP rule. It would be interested to compare the statistics of triplets or quadruplets of spikes timings and weight change under the proposed rule. against the corresponding biological observations (Froemke and Dan, 2002).

Future work should also attempt to reconcile the theory with neuroscience experiments showing more complex relationships between spikes and weight change, involving factors other than timing, such as firing rate, of course, but also synaptic cooperativity and depolarization (Feldman, 2012). In addition to these factors, some synaptic changes do not conform to the STDP pattern, either in sign (anti-Hebbian STDP) or in nature (for example incorporating a general Hebbian element as in the BCM rule). In this regard, although this work suggests that some spike timing behavior may be explained purely in terms of the rates trajectory, it remains an open question if (and where) precise timing of spikes remains essential to explain network-level learning behavior from a machine learning perspective. It is interesting to note in this regard how the BCM rule was adapted to account for the relative timing of spike triplets (Gjorgjieva *et al.*, 2011).
