Abstract

An (a, b, τ) streaming code is a packet-level erasure code that can recover under a strict delay constraint of τ time units, from either a burst of b erasures or else of a random erasures, occurring within a sliding window of time duration w. While rate-optimal constructions of such streaming codes are available for all parameters $\{a, b, \tau, w\}$ in the literature, they require in most instances, a quadratic, $O(\tau^2)$ field size. In this work, we make further progress towards field size reduction and present rate-optimal $O(\tau)$ field size streaming codes for two regimes: (i) $gcd(b, \tau + 1 - a) \geq a$ (ii) $\tau + 1 \geq a + b$ and $b \mod a \in \{0, a - 1\}$.

Index Terms

Streaming codes, low-latency communication, burst and random erasure correction, packet-level FEC.

I. Introduction

Ultra-Reliable, Low-Latency Communication (URLLC) is a principal focus area of 5G and is key to enabling many next-generation applications such as interactive streaming, industrial automation, multi-player gaming and disaster recovery. ARQ-based schemes, while ensuring reliability, are not suitable for low-latency communication due to their large round-trip delays. The naive solution of replication to ensure reliability leads to wastage of resources. Thus, the development of FEC schemes that can operate under a strict decoding-delay constraint is necessary for the setting up of a reliable, low-latency communication system. The streaming codes under discussion here, were developed with this aim in mind.

In [1] and [2], authors introduced the setting of streaming codes, which is as follows. There is an infinite stream of message packets $\{\underline{u}(t)\}_{t=0}^{\infty}$, $\underline{u}(t) \in \mathbb{F}_q^k$, which needs to be reliably transmitted from a transmitter to a receiver, where the channel can introduce packet losses. In order to tackle packet losses, coded packets which contain both message and parity parts are transmitted across the channel. We use the terminology message packet to denote the message part of the coded packet and similarly parity packet refers to the parity part of the coded packet. Let $\underline{x}(t) \in \mathbb{F}_q^n$ denote the coded packet transmitted at time t. Then $\underline{x}(t)^T \triangleq \begin{bmatrix} \underline{u}(t)^T & \underline{p}(t)^T \end{bmatrix}$, where $\underline{u}(t) \in \mathbb{F}_q^k$ is the message packet at time t and $\underline{p}(t) \in \mathbb{F}_q^{n-k}$ is the parity packet at time t. The parity packet $\underline{p}(t)$ at time t is a function only of $\{\underline{u}(\ell) \mid \ell \leq t\}$, due to the causal nature of the encoder. The initial channel model considered for streaming codes in [1] and [2] is such that in every sliding window of time duration $\tau + 1$, there can be a burst erasure of length at most b. Streaming code constructions are presented in [1] and [2], which permit recovery of each message packet with a delay of at most τ, in spite of the burst losses, i.e., $\underline{u}(t)$ is recovered by time $t + \tau$, for all t. In a subsequent work, Badr et al. [3] introduced the delay-constrained sliding-window (DC-SW) channel model, which is a tractable deterministic approximation of the popularly used Gilbert-Elliott (GE) channel model. Under the DC-SW channel model, within any sliding window of time duration w, there can be either at most a random erasures or else, a burst erasure of length $\leq b$. The paper [3] presented streaming code constructions which can recover every packet $\underline{u}(t)$ by time $t + \tau$ in presence of the DC-SW channel. It is to be noted that the channel parameters naturally satisfy: $a \leq b \leq \tau$. Without loss of generality, one can set $w = \tau + 1$ (see [3] or [4]). Hence

the DC-SW channel is parameterized by $\{a, b, \tau\}$. In the remainder of the paper, we use (a, b, τ) streaming code to refer to codes which can recover from all the permissible erasure patterns of $\{a, b, \tau\}$ DC-SW channel, under strict decoding delay constraint τ.

In [3], an upper bound on the rate R of an (a, b, τ) streaming code is provided. In [5], [6] it was shown that this upper bound is indeed achievable for all parameters. The optimal rate of an (a, b, τ) streaming code thus obtained is given by,

$$R_{\text{opt}} \triangleq \frac{\tau + 1 - a}{\tau + 1 - a + b}.$$

The papers [5], [6] presented first families of rate-optimal streaming code constructions and required a field size exponential in τ. In [4], an $O(\tau^2)$ field size non-explicit rate-optimal streaming code construction is presented for all possible $\{a, b, \tau\}$. The paper [4] also provided 4 additional constructions with $O(\tau)$ field size for restricted parameter sets (see Table I). An explicit quadratic field size streaming code construction for all parameters is presented in [7]. The rate-optimal streaming code constructions appearing in [2], [4]–[7] all employ a certain diagonal embedding (DE) technique introduced in [2]. The DE technique enables one to construct streaming codes by diagonally embedding the code symbols of a scalar block code in the packet stream. In a recent work [8], the authors introduced the technique of staggered diagonal embedding (SDE), which generalizes DE. Under the SDE approach, n code symbols of the scalar block code are dispersed across a span of $N \geq n$ successive packets. A linear field size rate-optimal streaming code construction for all $\{a, b, \tau\}$ such that $gcd(b, \tau + 1 - a) = b$ is presented in [8]. The study of SDE in [8] is restricted to the case $N \leq \tau + 1$. In the present paper, we explore the SDE technique beyond $N \leq \tau + 1$ and present new streaming code constructions, which require $O(\tau)$ field size and smaller packet length n, compared to existing constructions. As shown in Fig. 1, constructions in the present paper provide a significant range of new parameters $\{a, b, \tau\}$ over which linear field size is feasible.

Our Contributions:

- We provide necessary and sufficient conditions for SDE of a scalar code to result in an (a, b, τ) streaming code.
- We develop a new family of scalar codes which result in linear field size, rate-optimal (a, b, τ) streaming codes for two new regimes.
  - We use SDE to generate (a, b, τ) streaming codes for all $\{a, b, \tau\}$ with $gcd(b, \tau + 1 - a) \geq a$.
  - We show using DE (a special case of SDE where $n = N$) that the scalar code construction results in (a, b, τ) streaming codes whenever $\tau + 1 \geq a + b$ and $b \mod a = 0$ and a modified version of this scalar code works whenever $\tau + 1 \geq a + b$ and $b \mod a = a - 1$.

Organization of the Paper: The SDE framework is described in full generality in Section II. In Section III, we provide the construction of scalar block code to be used in conjunction with SDE or the special case of DE. We provide construction of linear field size streaming codes based on SDE technique in Section IV. In Section V, we show how the construction can be modified to come up with DE-based linear field size streaming codes.

Notation: We use the notation $[a : b]$ to denote $\{a, a + 1, \ldots, b - 1, b\}$. For any finite set $E \subseteq \mathbb{Z}$, we use $|E|$ to denote number of elements in E and $\max(E)$ to denote the largest element in E. Let $M \in \mathbb{F}_q^{k \times n}$, then by $M(i_1 : i_2, j_1 : j_2)$, we mean the sub-matrix of M comprising of rows whose indices lie in $[i_1 : i_2]$ and columns whose indices lie in $[j_1 : j_2]$. We use the notation I_k for the $k \times k$ identity matrix. For $V \subseteq \mathbb{F}_q^n$, span$\langle V \rangle$ denotes the linear span of V.

II. STAGGERED DIAGONAL EMBEDDING

In this section, we explain the staggered diagonal embedding technique introduced in [8], for constructing packet-level codes from scalar codes. Let $\mathbb{C}$ be an $[n, k]$ linear code over $\mathbb{F}_q$, with first k symbols forming an information set. Let $N \geq n$ be an integer and let $S \subseteq [0 : N - 1]$ be such that $|S| = n$. Let $S \triangleq \{s_0, s_1, \ldots, s_{n-1}\}$, where $0 = s_0 < s_1 < \cdots < s_{n-1} = N - 1$. We refer to $\mathbb{C}$ as the base code, S as the placement set and N as the dispersion span. The packet-level code resulting from SDE of scalar code $\mathbb{C}$ with the placement set S will be referred to as SDE$(\mathbb{C}, S)$. For $i \in [0 : n - 1]$, let $x_i(t)$ denote the ith component of the coded packet $\underline{x}(t)$ of the packet-level code SDE$(\mathbb{C}, S)$ (see Fig. 2 for an example). Then we have the following relation between component symbols:

$$\left(x_0(t + s_0), x_1(t + s_1), \cdots, x_{n-1}(t + s_{n-1}) \right) \in \mathbb{C}, \ \forall t. \tag{1}$$

Linear Field Size Streaming Code	Parameter Range
Construction A [4]	$b - a = 1$
Construction B [4]	$(\tau + a + 1) \geq 2b \geq 4a$
Construction C [4]	$a|b|(\tau + 1 - a)$
Construction D [4]	$b = 2a - 1$ and $b|(\tau + 2 - a)$
Simple Streaming Code [8]	$b|(\tau + 1 - a)$
SDE-based code (present paper)	$gcd(b, \tau + 1 - a) \geq a$
DE-based code (present paper)	$\tau + 1 - a \geq b$ and $b \mod a \in \{0, a - 1\}$

TABLE I: Parameters for which linear field size streaming codes are known.

Fig. 1: The figure depicts for all parameters $\{a, b, \tau\}$, where $a \leq b \leq \tau \leq 10$, the smallest field size streaming code known. The construction A ($b - a = 1$), B and D refer to the linear field size codes from [4] and SDE-based codes are the linear field size codes presented in this paper. For the rest of the valid parameters, best known codes require quadratic field size and can be found in [4], [7].

It is easy to see that the resultant packet-level code has rate $\frac{k}{n}$, which is same as that of $\mathbb{C}$. When $N = n$, we have $S = [0 : n - 1]$ and SDE reduces to DE.

For the packet-level code $SDE(\mathbb{C}, S)$ to be an (a, b, τ) streaming code, there are some conditions that it needs to satisfy. The Theorem 1 in [8] states such conditions for the case $N \leq \tau + 1$, whereas here in Theorem II.1, we provide necessary and sufficient conditions for the general case which includes $N > \tau + 1$.

For a streaming code, a lost packet $\underline{x}(t)$ must be recovered from admissible erasures by accessing all the available packets till time $t + \tau$. We need to translate this requirement in terms of the scalar code $\mathbb{C}$. Towards this, we first introduce the function $f_S : [0 : N - 1] \to [0 : n - 1]$ for a given placement set S, which is defined as:

$$f_S(j) \triangleq \max\{i : s_i \leq j\}.$$

We now define $r_i \triangleq f_S(\min\{s_i + \tau, N - 1\})$ for every index $i \in [0 : n - 1]$. During the recovery of ith code symbol, one can access only till r_ith code symbol. We will use the notation $f_S(J)$ to indicate the set $\{f_S(j) \mid j \in J\}$.

As an example, in Fig. 2, we have $n = 10, N = 14, \tau = 10$ and $S = \{0, 1, 3, 4, 6, 7, 9, 10, 12, 13\}$. In order to recover packet $\underline{x}(t)$ from a burst of size 6 starting at time t, one can access packets only till time $t + 10$. In terms of $\mathbb{C}$, as we have $r_0 = f_S(10) = 7$, for recovering c_0, symbols only till c_7 are accessible.

Theorem II.1. *Let $\mathbb{C}$ be an $[n, k]$ base code over $\mathbb{F}_q$ and let $S = \{s_0, s_1, \ldots, s_{n-1}\} \subseteq [0 : N - 1]$ be a placement set, where $s_0 = 0 < s_1 \cdots < s_{n-1} = N - 1$. The packet-level code $SDE(\mathbb{C}, S)$ is an (a, b, τ) streaming code iff $\mathbb{C}, S$ satisfy the following conditions:*
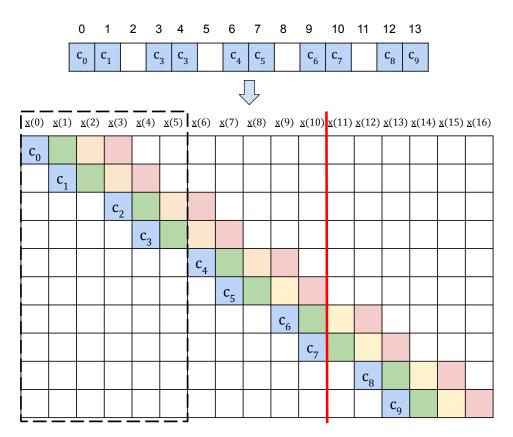

Fig. 2: SDE of an $[n = 10, k = 6]$ base code with placement set $S = \{0, 1, 3, 4, 6, 7, 9, 10, 12, 13\}$. Here $(c_0 \; c_1 \; \ldots \; c_9)$ is a codeword in the base code $\mathbb{C}$. It will be shown in Section IV that this results in an $(a = 2, b = 6, \tau = 10)$ streaming code. The black dashed window indicates a burst of size 6 starting at index 0 and the red line indicates the decoding delay i.e, recovery of 0th packet can access packets until index 10.

1) *Random erasure recovery : for all $i \in [0 : n - 1]$ and every $A \subseteq [i : r_i]$ such that $i \in A$, $|A| \leq a$, c_i is a linear combination of $\{c_j \mid j < i\} \cup \{c_j \mid j \in [i : r_i] \setminus A\}$ over $\mathbb{F}_q$, for all $\underline{c} = (c_0, c_1, \ldots, c_{n-1}) \in \mathbb{C}$.*

2) *Burst erasure recovery: for all $i \in [0 : n - 1]$ and every $B \subseteq [s_i : \min\{s_i + b - 1, N - 1\}]$ such that $s_i \in B$, c_i is a linear combination of $\{c_j \mid j < i\} \cup \{c_j \mid j \in [i : r_i] \setminus f_S(B)\}$ over $\mathbb{F}_q$, for all $\underline{c} = (c_0, c_1, \ldots, c_{n-1}) \in \mathbb{C}$.*

Proof: By definition, the packet-level code $\text{SDE}(\mathbb{C}, S)$ is an (a, b, τ) streaming code iff for every t and every $E \subseteq [t : t + \tau]$ such that $t \in E$ and either $|E| \leq a$ or $\max E - t \leq b - 1$, the packet $\underline{x}(t)$ is recoverable from $\{x(t') \mid t' < t$ or $t' \in [t : t + \tau] \setminus E\}$. Let $x_i(t)$ be the i-th component of the packet $\underline{x}(t)$. Since the packets are coded using $\text{SDE}(\mathbb{C}, S)$, by (1), the following condition is satisfied for every $i \in [0 : n - 1]$:

$$(x_0(t - s_i + s_0), \cdots, x_i(t), \cdots, x_{n-1}(t - s_i + s_{n-1})) \triangleq \underline{c} \in \mathbb{C}.$$

For any erasure set $E \subseteq [t : t + \tau]$ such that $t \in E$ and $|E| \leq a$, the codeword $\underline{c}$ observes erasures across coordinates indexed by $A \triangleq f_S(\{e + s_i - t \mid e \in E, \; e + s_i - t \leq N - 1\}) \subseteq [i : r_i]$. For any such erasure E, the symbols $x_i(t) \triangleq c_i$ for all $i \in [0 : n - 1]$, can be recovered, iff condition 1 holds. Now, for any erasure set $E \subseteq [t : t + \tau]$ such that $t \in E$, $\max(E) - t \leq b - 1$, let $B \triangleq \{e + s_i - t \mid e \in E, \; e + s_i - t \leq N - 1\}$. The erasures that the codeword $\underline{c}$ observes are given by $f_S(B)$ and the recovery of symbols $x_i(t)$ for all $i \in [0 : n - 1]$ is ensured iff condition 2 holds. Therefore conditions 1 and 2 are necessary and sufficient conditions for $\text{SDE}(\mathbb{C}, S)$ to result in an (a, b, τ) streaming code.

□

A. Equivalent Conditions on Parity Check (P-C) Matrix

Motivated by the p-c-matrix-based properties for DE-based (a, b, τ) streaming codes given in [4], we list down here analogous conditions for SDE-based streaming codes. These conditions will be used in proving that the linear field size code to be presented in Section IV is an (a, b, τ) streaming code. We first state, without proof, a well-known result that is useful in coming up with these conditions.

Lemma II.2. *Let $\mathbb{C}$ be an $[n, k]$ linear code over $\mathbb{F}_q$ and let $H \triangleq [\underline{h}_0 \ \underline{h}_1 \ \ldots \ \underline{h}_{n-1}] \in \mathbb{F}_q^{(n-k) \times n}$ be a p-c matrix for $\mathbb{C}$, where $\underline{h}_i \in \mathbb{F}_q^{n-k}$ denotes the ith column of H. Let $E \subseteq [0 : n-1]$ be an erasure set such that $i \in E$, then the code symbol c_i can be recovered iff $\underline{h}_i \notin span \left\langle \{ \underline{h}_j \mid j \in E \setminus \{i\} \} \right\rangle$.*

Let $\mathbb{C}$ be an $[n, k]$ linear code over $\mathbb{F}_q$ and $P \subseteq [0 : n-1]$. Then the punctured code $\mathbb{C}|_P$ is the code of block length $|P|$ obtained by deleting all the coordinates in $[0 : n-1] \setminus P$. Let H be a p-c matrix for $\mathbb{C}$ and $H^{(i)} \triangleq [\underline{h}_0^{(i)} \ \ldots \ \underline{h}_{r_i}^{(i)}]$ be the p-c matrix for $\mathbb{C}|_{[0:r_i]}$, for all $i \in [0 : n-1]$. Here $\underline{h}_j^{(i)}$ denotes jth column of $H^{(i)}$. Using Lemma II.2, the recovery conditions in Theorem II.1 can be restated in terms of these p-c matrices and placement set S as follows:

1) Random erasure recovery: for all $i \in [0 : n-1]$ and every $A \subseteq [i : r_i]$ such that $i \in A$, $|A| \leq a$,
   - if $r_i < n-1$, $\underline{h}_i^{(i)} \notin span \langle \{ \underline{h}_j^{(i)} \mid j \in A \setminus \{i\} \} \rangle$,
   - else if $r_i = n-1$, $\{ \underline{h}_j \mid j \in A \}$ is a linearly independent set.
2) Burst erasure recovery: for all $i \in [0 : n-1]$ and every $B \subseteq [s_i : \min\{s_i + b - 1, N - 1\}]$ such that $s_i \in B$,
   - if $r_i < n-1$, $\underline{h}_i^{(i)} \notin span \left\langle \{ \underline{h}_j^{(i)} \mid j \in f_S(B) \setminus \{i\} \} \right\rangle$,
   - else if $r_i = n-1$, $\{ \underline{h}_j \mid j \in f_S(B) \}$ is a linearly independent set.

We now state a result which makes checking these p-c conditions easier in some cases. We will make use of this result repeatedly in the proof of Theorem IV.1.

Lemma II.3. *Let $i \in [p : r_p]$ and $T \subseteq [i + 1 : r_i]$. If $\underline{h}_i^{(p)} \notin span \left\langle \{ \underline{h}_j^{(p)} \mid j \in T \cap [i + 1 : r_p] \} \right\rangle$, then $\underline{h}_i^{(i)} \notin span \left\langle \{ \underline{h}_j^{(i)} \mid j \in T \} \right\rangle$.*

Proof: Note that $i \geq p \implies r_i \geq r_p$ and hence $H^{(p)}$ is a sub-matrix of $H^{(i)}$ as shown below. If $r_i = r_p$, the statement trivially holds. For $r_i > r_p$, $H^{(i)}$ has the following structure:

$$H^{(i)} \ = \ \begin{bmatrix} H^{(p)} & 0 \\ M_1 & M_2 \end{bmatrix} = \begin{bmatrix} \underline{h}_0^{(i)} & \underline{h}_1^{(i)} & \cdots & \underline{h}_{r_i}^{(i)} \end{bmatrix}.$$

Suppose the statement doesn't follow then:

$$\underline{h_i}^{(i)} \ = \ \sum_{j \in T} a_j \underline{h}_j^{(i)}.$$

By equating rows where columns $h_{r_p+1}^{(i)}, \cdots, h_{r_i}^{(i)}$ have zeros we have:

$$\underline{h_i}^{(p)} \ = \ \sum_{j \in T \cap [i+1, r_p]} a_j \underline{h}_j^{(p)}.$$

This contradicts our assumption that $h_i^{(p)} \notin span \left\langle \{ \underline{h}_j^{(p)} \mid j \in T \cap [i + 1 : r_p] \} \right\rangle$. $\square$

III. BUILDING BLOCKS

In this section, we provide a construction of the scalar base code, which will be used in conjunction with SDE to obtain rate-optimal linear field size (a, b, τ) streaming codes.

Definition III.1 (Zero-band MDS Generator Matrix). A $k \times n$ matrix $Z = (z_{ij})_{i \in [0:k-1], j \in [0:n-1]}$ is a zero-band MDS generator matrix if:

1) Z is a generator matrix for an $[n, k]$ MDS code and,

2) $z_{ij} = 0$, $\forall \{i, j\}$ such that $j \in [i+1 : i+k-1](mod \; n)$.

Note that $z_{ij} \neq 0$, $\forall \{i, j\}$ such that $j \notin [i+1 : i+k-1](mod \; n)$. Otherwise, it would contradict the minimum distance of MDS code being equal to $n - k + 1$.

$$\begin{bmatrix} * & 0 & 0 & * & * & * \\ * & * & 0 & 0 & * & * \\ * & * & * & 0 & 0 & * \end{bmatrix}$$

Fig. 3: The structure of a 3×6 zero-band MDS generator matrix. Here * is a place-holder for non-zero field elements.

For every set of positive integers $\{k, n\}$ such that $n \geq k$, a $k \times n$ zero-band MDS generator matrix can be explicitly constructed over $\mathbb{F}_q$, if $q \geq n$ (for instance, see [4]).

Definition III.2 (Super-regular Matrix). A $k \times n$ matrix C is a super-regular matrix if every square sub-matrix of C is invertible.

It is a well-known result [9] that a $k \times n$ Cauchy matrix is super-regular and can always be explicitly constructed over $\mathbb{F}_q$, with $q \geq k + n$, for all positive integers k, n.

Construction III.1. Here we construct an $[n = \rho - a + r, \; k = \rho - a]$ linear block code $\mathbb{C}_{a,r,\rho}$ for all $\{a, r, \rho\}$ such that $r = \ell a$, for some integer $\ell \geq 1$, and $r < \rho$. Let $Z = [Z_1 \; Z_2]$ be an $a \times 2a$ zero-band MDS generator matrix, where $Z_1 = Z(0 : a-1, \; 0 : a-1)$ and $Z_2 = Z(0 : a-1, \; a : 2a-1)$. Let C be an $r \times (\rho - r)$ Cauchy matrix. We now describe an $r \times n$ p-c matrix H of $\mathbb{C}_{a,r,\rho}$ through a series of steps.

1) Initialize H to be the $r \times n$ all-zero matrix,
2) set $H(0 : a-1, \; 0 : a-1) = I_a$,
3) set $H(ia : ia+a-1, \; ia : ia+a-1) = Z_1$, $\forall i \in [1 : \ell-1]$,
4) set $H(0 : r-1, \; r : \rho-1) = C$,
5) set $H(ia : ia+a-1, \; \rho+(i-1)a : \rho+(i-1)a+a-1) = Z_2$, $\forall i \in [1 : \ell-1]$.

.

IV. LINEAR FIELD SIZE CONSTRUCTION FOR $gcd(b, \tau + 1 - a) \geq a$

In this section, we present a linear field size rate-optimal (a, b, τ) streaming code construction for all $\{a, b, \tau\}$ satisfying $gcd(b, \tau + 1 - a) = a + g \geq a$, where g is a non-negative integer. Clearly, there exist positive integers

ℓ, m such that $b = \ell(a + g)$, $\tau + 1 - a = m(a + g)$ and $gcd(m, \ell) = 1$. It also follows that $m \geq \ell$, otherwise $\tau + 1 = m(a + g) + a \leq b$. This is not possible as $b \leq \tau$.

Now, we will use $\mathbb{C}_{a,\ell a,(m+1)a}$ (see Construction III.1) as the base code. It can be easily seen that $\mathbb{C}_{a,\ell a,(m+1)a}$ is an $[n = (m + \ell)a,\ k = ma]$ code and its rate $R = \frac{m}{m+\ell} = \frac{\tau+1-a}{\tau+1-a+b} = R_{\text{opt}}$. We remark that both the matrices C and Z used in the construction exist over $\mathbb{F}_q$ if $q \geq (m + 1)a$ and hence, $\mathbb{C}_{a,\ell a,(m+1)a}$ requires only a field of size $q \geq (m + 1)a = \frac{a(\tau+1+g)}{a+g} = O(\tau)$. For SDE, we fix the dispersion span $N = (m + \ell - 1)(a + g) + a$ and choose the placement set:

$$S_{a,b,\tau} = \bigcup_{i=0}^{i=m+\ell-1} [i(a + g) : i(a + g) + a - 1]. \tag{2}$$

It can be clearly verified that $|S_{a,b,\tau}| = (m + \ell)a = n$.

A. An Example: $\{a = 2, b = 6, \tau = 10\}$

Here $gcd(b, \tau+1-a) = 3$. Hence, we have $m = 3, \ell = 2, g = 1, S_{2,6,10} = \{0, 1, 3, 4, 6, 7, 9, 10, 12, 13\}, N = 14$ and $\mathbb{C}_{2,4,8}$ is an $[10, 6]$ code. The p-c matrix H of $\mathbb{C}_{2,4,8}$ is given by:

$$H = \begin{bmatrix} 1 & 0 & 0 & 0 & c_{00} & c_{01} & c_{02} & c_{03} & 0 & 0 \\ 0 & 1 & 0 & 0 & c_{10} & c_{11} & c_{12} & c_{13} & 0 & 0 \\ 0 & 0 & z_{00} & 0 & c_{20} & c_{21} & c_{22} & c_{23} & z_{02} & z_{03} \\ 0 & 0 & z_{10} & z_{11} & c_{30} & c_{31} & c_{32} & c_{33} & 0 & z_{13} \end{bmatrix},$$

such that:

$$Z = \begin{bmatrix} z_{00} & 0 & z_{02} & z_{03} \\ z_{10} & z_{11} & 0 & z_{13} \end{bmatrix}, C = \begin{bmatrix} c_{00} & c_{01} & c_{02} & c_{03} \\ c_{10} & c_{11} & c_{12} & c_{13} \\ c_{20} & c_{21} & c_{22} & c_{23} \\ c_{30} & c_{31} & c_{32} & c_{33} \end{bmatrix}$$

are 2×4 zero-band MDS generator matrix, 4×4 Cauchy matrix respectively. Both these matrices can be constructed over $\mathbb{F}_8$. In order to prove that the packet-level code constructed by SDE of $\mathbb{C}_{2,4,8}$ with placement set $S_{2,6,10}$ is a rate-optimal streaming code, we only have to show that $\mathbb{C}_{2,4,8}$ along with $S_{2,6,10}$ satisfy both random and burst erasure recovery conditions laid out in Section II. In this case, we have: $r_0 = 7, r_1 = 7, r_i = 9, \forall i \in [2 : 9]$.

Random Erasure Recovery

- $r_i < 9 \implies i \in \{0, 1\}$

The p-c matrix of punctured code $\mathbb{C}_{2,4,8}|_{[0:7]}$ takes the form $\begin{bmatrix} 1 & 0 & c_{00} & c_{01} & c_{02} & c_{03} \\ 0 & 1 & c_{10} & c_{11} & c_{12} & c_{13} \end{bmatrix}$, after removing columns $2, 3$ that are all-zero. This matrix can be shown to be a generator matrix for a $[6, 2]$ MDS code and hence no two columns are linearly dependent. Thus, random erasure recovery condition is satisfied for $i = 0, 1$.

- $r_i = 9 \implies i \in [2 : 9]$

Here we need to show that any two columns among last 8 columns of H are linearly independent. It can be easily seen that no two among columns $2, 3, 8$ and 9 can be linearly dependent as Z is a generator matrix for a $[4, 2]$ MDS code. Since every square sub-matrix of a Cauchy matrix is invertible, any two among columns $4, 5, 6$ and 7 are linearly independent. Also, if we pick one column with index in $\{2, 3, 8, 9\}$ and another column with index in $\{4, 5, 6, 7\}$, they are linearly independent because they have different support. Thus we have showed that no two columns of $H(0 : 3,\ 2 : 9)$ are linearly dependent, thereby showing that random erasure condition is satisfied for $i \in [2 : 9]$.

Burst Erasure Recovery

For $j \in [0:8]$, consider any consecutive $b = 6$ columns in $[0:13]$ of the form $B \triangleq [j:j+5]$. The placement set $S_{2,6,10}$ ensures that $|f_{S_{2,6,10}}(B)| = 4$. Hence it follows that any burst of size 6 results in a loss of 4 consecutive symbols for every underlying codeword of the base code (for instance, see Fig. 2).

- $r_i < 9 \implies i \in \{0,1\}$

In $H(0:1, 0:7)$, which is the p-c matrix of $\mathbb{C}_{2,6,10}|_{[0:7]}$, it can be easily seen that column 0 is not a linear combination columns $1, 2$ and 3 due to disjoint support. Similarly, column 1 of $H(0:1, 0:7)$ does not lie in span of columns $2, 3$ and 4, due to difference in support. Thus, for $i = 0, 1$ burst erasure recovery condition is satisfied.

- $r_i = 9 \implies i \in [2:9]$

In order to show that burst erasure property holds for $i = [2:9]$, it suffices to prove that any collection of 4 consecutive columns among last 8 columns of H forms a linear independent set. Equivalently, one needs to show that $H(0:3, i:i+3)$ is invertible, for all $i \in [2:6]$. As $\begin{bmatrix} z_{00} & 0 \\ z_{10} & z_{11} \end{bmatrix}$ and $\begin{bmatrix} c_{00} & c_{01} \\ c_{10} & c_{11} \end{bmatrix}$ are both invertible,

$H(0:3, \ 2:5)$ is invertible. As $\begin{bmatrix} c_{00} & c_{01} & c_{02} \\ c_{10} & c_{11} & c_{12} \\ c_{20} & c_{21} & c_{22} \end{bmatrix}$ is invertible and $z_{11} \neq 0$, invertibility of $H(0:3, \ 3:6)$ follows.

The matrix $H(0:3, \ 4:7)$ is the Cauchy matrix C and is hence invertible. The invertibility of $\begin{bmatrix} c_{01} & c_{02} & c_{03} \\ c_{11} & c_{12} & c_{13} \\ c_{31} & c_{32} & c_{33} \end{bmatrix}$

together with $z_{02} \neq 0$ results in $H(0:3, \ 5:8)$ being invertible. Since $\begin{bmatrix} c_{02} & c_{03} \\ c_{12} & c_{13} \end{bmatrix}$ and $\begin{bmatrix} z_{02} & z_{03} \\ 0 & z_{13} \end{bmatrix}$ are both invertible, $H(0:3, \ 6:9)$ is invertible. Thus, we have proved that the packet-level code $SDE(\mathbb{C}_{2,4,8}, S_{2,6,10})$ is a $(a = 2, b = 6, \tau = 10)$ rate-optimal streaming code and can be constructed over $\mathbb{F}_8$. This example is generalized in the Theorem stated below.

Theorem IV.1. *For any set of parameters* $\{a, b, \tau\}$ *such that* $a + g = \gcd(b, \tau + 1 - a) \geq a$, *let* $\ell = \frac{b}{a+g}$ *and* $m = \frac{\tau + 1 - a}{a+g}$, *then the packet level code* $SDE(\mathbb{C}_{a, \ell a, (m+1)a}, S_{a,b,\tau})$, *is an* (a, b, τ) *streaming code that is rate-optimal and* $O(\tau)$ *field size.*

Proof: When $\gcd(b, \tau + 1 - a) = b$, we have $\ell = 1$ and $\mathbb{C}_{a,a,(m+1)a}$ is an $[(m+1)a, a]$ MDS code. The packet level code for $\ell = 1$ case is exactly same as the MDS base code construction in [8]. We skip the proof for $\ell = 1$ case since it is provided in [8]. Throughout the reminder of the proof we assume $\ell > 1$.

Let H denote the $\ell a \times (m+\ell)a$ p-c matrix of $\mathbb{C}_{a,\ell a,(m+1)a}$ and $S_{a,b,\tau} = \{s_0, \cdots, s_{n-1}\}$ is as defined as shown in equation (2). Therefore $N - 1 = s_{n-1} = (m+\ell-1)(a+g) + a - 1$. The index of further most symbol accessible for recovery of symbol at index ja is given by:

$$\begin{aligned} r_{ja} &= f_{S_{a,b,\tau}}(\min\{s_{ja} + \tau, N - 1\}) \\ &= f_{S_{a,b,\tau}}(\min\{(j+m)(a+g) + a - 1, N - 1\}) \\ &= \begin{cases} (j+m+1)a - 1 & j < \ell \\ (m+\ell)a - 1 & j \geq \ell. \end{cases} \end{aligned}$$

The values of r_{ja} determines the punctured codes which we need to consider to prove the theorem.

We will now show that burst B in $[0, N-1]$ of size b results in burst of size ℓa in $[0, n-1]$. Let $i = ja + j' \in [0:n-1]$ where $j' \in [0:a-1]$ and $B = [s_i : s_i + b - 1] \subseteq [0:N-1]$ then:

$$\begin{aligned} f_{S_{a,b,\tau}}(B) &= f_{S_{a,b,\tau}}(\{j(a+g) + j_0 \mid j_0 \in [j' : j' + \ell(a+g) - 1]\}) \\ &= f_{S_{a,b,\tau}}(\{j(a+g) + j_0 \mid j_0 \in [j' : a - 1]\}) \cup \\ &\quad \cup_{j_1=j+1}^{j+\ell-1} f_{S_{a,b,\tau}}(\{j_1(a+g) + j_0 \mid j_0 \in [0 : a - 1]\}) \cup \\ &\quad f_{S_{a,b,\tau}}(\{(j+\ell)(a+g) + j_0 \mid j_0 \in [0 : j' - 1]\}) \end{aligned}$$

$$\begin{aligned}
&= [i : (j+1)a - 1] \cup \left(\cup_{j_1=j+1}^{j+\ell-1}[j_1 a : (j_1+1)a - 1] \right)\\
&\quad \cup [(j+\ell)a : (j+\ell)a + j' - 1]\\
&= [i : i + \ell a - 1].
\end{aligned}$$

Therefore, by Theorem II.1 and the fact that $f_{S_{a,b,\tau}}(B) = [i : i + \ell a - 1]$, it is enough to show that for all $i \in [0 : n-1]$, c_i can be recovered from $\{c_j \mid j < i\} \cup \{c_j \mid j \in [i + \ell a : r_i]\}$ to prove burst erasure recovery.

We divide the proof into three parts based on the value of i.

1) For $i \in [0 : a-1]$, we show how to recover symbol i by accessing symbols only until $r_0 = (m+1)a - 1$, though we have access until r_i-th symbol. The parity check matrix that represents the punctured code $\mathbb{C}_{a,\ell a,(m+1)a} \mid_{r_0}$ is given by:

$$H^{(0)} = \left[\begin{array}{ccc} I_a & 0_{a \times (\ell-1)a} & C(0 : a-1, 0 : (m+1-\ell)a - 1) \end{array}\right]$$

Random Erasure Recovery: Let $A \subseteq [i : r_i]$ be a set of erasures such that $|A| \le a$. Let $A_0 = [i : r_0] \cap A$. Then it is clear that $|A_0| \le a$. Clearly the i-th column in $H^{(0)}$, $h_i^{(0)}$ doesn't belong to span of any $a-1$ other columns in $[i+1, r_0]$ as C is a Cauchy matrix.

Burst Erasure Recovery: Let $B = [s_i, s_i + b - 1]$. This will result in erasures $f_{S_{a,b,\tau}} = [i, i + \ell a - 1]$ in the base code. We will show that the code symbol c_i can be recovered by accessing symbols until r_0. Here, $h_i^{(0)}$ is clearly not in span of $\{h_{i+1}^{(0)}, \cdots, h_{a-1}^{(0)}, h_{\ell a}^{(0)}, \cdots, h_{\ell a+i}^{(0)}\}$, again due to super-regular property of C, and hence c_i can be recovered.

2) For $i \in [ja, (j+1)a - 1]$ with $j \in [1 : \ell - 2]$ we show how to recover c_i by accessing symbols only until $r_{ja} = (j+m+1)a - 1$ though we have access until r_i. The parity check matrix that represents the punctured code $\mathbb{C}_{a,\ell a,(m+1)a} \mid_{r_{ja}}$, $H^{(ja)}$ is given by:

$$H^{(ja)} = \left[\begin{array}{ccc|c|c|ccc}
I_a & & & & & & &\\
\hline
& Z_1 & & & & Z_2 & &\\
\hline
& & \ddots & 0 & C(0 : (j+1)a - 1, 0 : (m+1-\ell)a - 1) & & \ddots &\\
\hline
& & Z_1 & & & & & Z_2
\end{array}\right]$$

It can observed that columns of $H^{(ja)}$ with index in $[(j+1)a : \ell a - 1]$ are all-zero columns and hence erasures in these columns can be neglected.

Random Erasure Recovery: Let $A \subseteq [i : r_{ja}] \setminus [(j+1)a : \ell a - 1]$ with $|A| \le a$ and $i \in A$ be such that $\underline{h}_i^{(ja)} = \sum_{p \in A \setminus \{i\}} u_p \underline{h}_p^{(ja)}$, for some assignment of $u_p \in \mathbb{F}_q$. In $\underline{h}_i^{(ja)}$ the first a rows are zeros and columns with index in $[\ell a : (m+1)a - 1]$ are the only columns with non-zero entries in first a rows. If one column from $[\ell a : (m+1)a - 1]$ is involved in the linear combination, then a other columns from $[\ell a : (m+1)a - 1]$ are required to obtain zeros in first a rows, because of the super-regular property. Hence, we have $u_p = 0$ for all $p \in A \cap [\ell a : (m+1)a - 1]$. Also, $\underline{h}_i^{(ja)}$ has zeros in rows $[a : ja - 1]$. It can be seen that no collection of $\le a - 1$ columns from $[(m+1)a : r_{ja} - a]$, can linearly combine to form zeros in rows $[a : ja - 1]$, because of the support structure of columns and MDS property of Z implying that $u_p = 0$ for all $p \in A \cap [\ell a, r_{ja} - a]$. The remaining columns $A \cap ([i+1, (j+1)a - 1] \cup [r_{ja} - a + 1, r_{ja}])$ can not span i-th column, again due to MDS property of Z. Therefore it is not possible to have: $h_i^{(ja)} = \sum_{p \in A \setminus \{i\}} u_p \underline{h}_p^{(ja)}$. Hence c_i is recoverable from $[i : r_{ja}] \setminus A$ for any $A \subseteq [i : r_{ja}]$ such that $i \in A$ and $|A| \le a$.
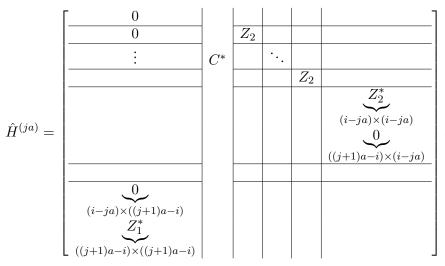

Burst Erasure Recovery: Let $B = [s_i : s_i + b - 1]$, then the base code sees erasures $B_0 = [i : i + \ell a - 1]$. We want to show that $\underline{h}_i^{(ja)}$ doesn't belong to span of columns of $H^{(ja)}$ indexed by elements in $B_0 \setminus \{i\}$. It is enough to consider columns in $B_0 \setminus [(j+1)a : \ell a - 1]$ as the columns $[(j+1)a : \ell a - 1]$ are all zero.

(a): For $i \leq (m - \ell + 1)a$. The submatrix formed by columns $B_0 \setminus [(j+1)a : \ell a - 1]$ in matrix $H^{(ja)}$ is of the form:

$$\hat{H}^{(ja)} = \left[\begin{array}{c|c} 0 & C(0 : i-1, 0 : i-1) \\ \hline Z_1(i - ja : a - 1, i - ja : a - 1) & C(i : (j+1)a - 1, 0 : i - 1) \end{array} \right].$$

Note that the number of rows of this matrix is same as the rows of $H^{(ja)}$ which is $(j+1)a$ and the number of columns is given by $\ell a - (\ell a - (j+1)a) = (j+1)a$. Clearly this matrix is invertible as both $C(0 : i - 1, 0 : i - 1)$ and $Z_1(i - ja : a - 1; i - ja : a - 1)$ are invertible. The invertibility of $Z_1(i - ja : a - 1; i - ja : a - 1)$ can be easily argued using MDS property of Z and lower triangular structure of Z_1.

(b): For $i > (m - \ell + 1)a$. Let $i = ja + j'$ for some $j' \in [0, a - 1]$, then $i + \ell a - 1 = (j + \ell)a + j' - 1$. Here $j_1 = (j + \ell - m - 1)$ is the number of Z_2 blocks that appear in the submatrix formed by columns $B_0 \setminus [(j+1)a : \ell a - 1]$ of $H^{(ja)}$. The form of this submatrix is given by:

$$\hat{H}^{(ja)} = \begin{bmatrix} \begin{array}{c|c|c} \begin{matrix} 0 \\ 0 \\ \vdots \\ \ \\ \ \\ \ \\ \ \end{matrix} & C^* & \begin{matrix} Z_2 & & \\ & \ddots & \\ & & Z_2 \\ & & \underbrace{Z_2^*}_{(i-ja)\times(i-ja)} \\ & & \underbrace{0}_{((j+1)a-i)\times(i-ja)} \end{matrix} \\ \hline \begin{matrix} \underbrace{0}_{(i-ja)\times((j+1)a-i)} \\ \underbrace{Z_1^*}_{((j+1)a-i)\times((j+1)a-i)} \end{matrix} & & \end{array} \end{bmatrix}.$$

where $Z_1^* = Z_1(i - ja : a - 1, i - ja : a - 1)$, $Z_2^* = Z_2(0 : i - ja - 1, 0 : i - ja - 1)$ and $C^* = C(0 : (j+1)a - 1, 0 : (m + 1 - \ell)a - 1)$. Consider the rows of $\hat{H}^{(ja)}$ with non-zero support only in Cauchy columns. These $(m - \ell + 1)a$ rows are indexed by $[0, a - 1] \cup [i - (m - \ell)a : i - 1]$. The submatrix of C, denoted by $\hat{C}$, containing only these $(m - \ell + 1)a$ rows is square and hence invertible. The lower triangular structure of Z_1 and upper triangular structure of Z_2 along with MDS property of Z gives invertibility of Z_1^* and Z_2^* respectively. Note that $\hat{H}(ja)$ contains a columns from Z_1^* and Z_2^* together and from the structure of Z it follows that there is row in $\hat{H}^{(ja)}$ with non-zero entry from both Z_1^* and Z_2^*. By row and column permutation, the non-Cauchy columns of $\hat{H}$ can be made to a block diagonal matrix, with each block invertible. Using this and invertibility of $\hat{C}$, it can be inferred that the matrix $\hat{H}^{(ja)}$ is invertible.

Thus, we have proved that the submatrix formed by columns $B_0 \setminus [(j+1)a : \ell a - 1]$ in matrix $H^{(ja)}$ is is invertible and hence $\underline{h}_i^{(ja)}$ doesn't lie in span of columns of $H^{(ja)}$ indexed by $B_0 \setminus \{i\}$.

3) For $i \in [(\ell - 1)a : (m + \ell)a - 1]$, the value of $r_i = (m + \ell)a - 1$.

$$H(0 : r - 1, \ (\ell - 1)a : (m + \ell)a - 1) = \begin{bmatrix} \begin{array}{c|c|c} & & \begin{matrix} Z_2 & & \\ & \ddots & \\ & & \end{matrix} \\ \cline{1-1} & C_{r \times (m+1-\ell)a} & \\ \hline Z_1 & & \begin{matrix} \\ & & Z_2 \end{matrix} \end{array} \end{bmatrix}.$$

Random Erasure Recovery: It is to be shown that any collection of a columns of H with index in $[(\ell - 1)a : (m + \ell)a - 1]$ forms a linearly independent set. Suppose there exists $A \subseteq [(\ell - 1)a : (m + \ell)a - 1]$ with $|A| \leq a$

such that $\sum_{j \in A} u_j \underline{h}_j = 0$, $u_j \in \mathbb{F}_q$. Since columns with index in $[\ell a : (m+1)a-1]$ are the only columns with non-zero entries in first a rows, if one column from $[\ell a : (m+1)a-1]$ is part of the linear combination, then a other columns from $[\ell a : (m+1)a-1]$ are required to obtain zeros in first a rows, because of the super-regular property. Hence, $u_j = 0$ for all $j \in A \cap [\ell a : (m+1)a-1]$. Now, because of the MDS property of Z and support structure of columns, no collection of a columns with index in $[(m+1)a : (m+\ell)a - 1] \cup [(\ell - 1)a : \ell a - 1]$ can linearly dependent. Thus we have $u_j = 0$ for all $j \in A$. Therefore all the columns indexed by elements in A are linearly independent and hence random erasure recovery is guaranteed.

Burst Erasure Recovery: To prove this property, it suffices to show that the square sub-matrix formed any $r = \ell a$ consecutive columns of $H(0 : r-1, \ (\ell-1)a : (m+\ell)a-1)$ is invertible. Consider some set B_0 consisting of r consecutive integers from $[(\ell-1)a : (m+\ell)a-1]$. Let $\hat{H}$ be the submatrix of $H(0 : r-1, \ (\ell-1)a : (m+\ell)a-1)$ which is formed by collecting columns indexed by B_0.

It can be verified that $\hat{H}$ has $\left| B_0 \cap [\ell a : (m+1)a - 1] \right|$ rows which has support only in the Cauchy part and the sub-matrix of C formed by these rows is a square and invertible. By row and column permutation, the non-Cauchy columns of $\hat{H}$ (if they exist) can be made to a block diagonal matrix. Since $m - \ell + 1 \geq 1$, less than a columns with index in $[(\ell-1)a : \ell a - 1] \cup [(m+\ell-1)a : (m+\ell)a - 1]$ are part of $\hat{H}$. This ensures that no more than a consecutive columns of same Z matrix are involved in $\hat{H}$. Now, using this fact and properties of Z, it can easily argued that each of these block are invertible, thus proving invertibility of $\hat{H}$.

□

V. DIAGONAL EMBEDDING BASED CONSTRUCTIONS

In the streaming code construction presented in Section II, when $gcd(b, \tau + 1 - a) = a$, we have $N = n$ and SDE reduces to DE. The DE of same scalar code given by Construction III.1 results in a streaming code even when $gcd(b, \tau + 1 - a) < a$ as long as $a | b, \tau + 1 - a \geq b$. We also come up with a modified scalar code shown in construction V.2 whose DE results in streaming codes when $b \mod a = a - 1$ and $\tau + 1 - a \geq b$.

A. $a|b$ and $\tau + 1 - a \geq b$

Let $\{a, b, \tau\}$ be such that $\tau + 1 - a \geq b$ and $b = \ell a$, where $\ell \geq 1$ is a positive integer. Then, DE of $\mathbb{C}_{a,b,\tau+1}$ results in rate-optimal (a, b, τ) streaming code over a finite field of size $q \geq \tau + 1$. We remark that rate of $\mathbb{C}_{a,b,\tau+1}$, $R = \frac{\tau+1-a}{\tau+1-a+b} = R_{\text{opt}}$. The example shown in previous section $\mathbb{C}_{2,4,8}$ results in $(a = 2, b = 4, \tau = 7)$ streaming code by DE. Similarly, DE of $\mathbb{C}_{2,4,7}$ results in an $(a = 2, b = 4, \tau = 6)$ streaming code. With respect to the parameters $\{a = 2, b = 4, \tau = 6\}$, note that we cannot invoke the construction in Section IV as $gcd(b, \tau + 1 - a) = 1 < a$.

Theorem V.1. *For any set of parameters $\{a, b, \tau\}$ such that $\tau + 1 - a \geq b$ and $a|b$, the DE of $\mathbb{C}_{a,b,\tau+1}$ gives a rate-optimal $O(\tau)$ field size (a, b, τ) streaming code.*

Proof: Random erasure recovery proof follows along the same line of proof for Theorem II.1. The restriction $\tau + 1 \geq b + a$ ensures that no more than a coordinates associated with same Z matrix are involved in the same burst erasure. Under this restriction all the arguments in burst erasure recovery proof of Theorem II.1 follows here as well.

□

B. $b \mod a = a - 1$ and $\tau + 1 - a \geq b$

Assume that $\{a, b, \tau\}$ is such that $\tau + 1 - a \geq b$ and $b = \ell a + a - 1$, where $\ell \geq 1$ is a positive integer. Then, we come up with an $[n = \tau + 1 - a + b, \ k = \tau + 1 - a]$ linear code $\mathbb{C}^I_{a,b,\tau+1}$ over a finite field of size $q \geq \tau + 1$ and using DE we obtain a rate-optimal (a, b, τ) streaming code. Note that rate of $\mathbb{C}^I_{a,b,\tau+1}$, $R = \frac{\tau+1-a}{\tau+1-a+b} = R_{\text{opt}}$.

Construction V.2. *Let $Z = [Z_1 \ Z_2]$ be an $a \times 2a$ zero-band MDS generator matrix, where $Z_1 = Z(0 : a - 1, \ 0 : a - 1)$ and $Z_2 = Z(0 : a - 1, \ a : 2a - 1)$, and C be a $b \times (\tau + 1 - b)$ Cauchy matrix. Also, we define $Z_2^* = Z_2(0 : a - 2, \ 0 : a - 2)$. The $b \times n$ p-c matrix H of $\mathbb{C}^I_{a,b,\tau+1}$ is given by following steps.*

1) *Initialize H to be the $b \times n$ all-zero matrix,*
2) *$H(0 : a - 2, \ 0 : a - 2) = I_{a-1}$,*
3) *$H(ia - 1 : ia + a - 2, \ ia - 1 : ia + a - 2) = Z_1, \ \forall i \in [1 : \ell]$,*

4) $H(0 : b - 1, \ b : \tau) = C$,

5) $H(a - 1 : 2a - 3, \ \tau + 1 : \tau + a - 1) = Z_2^*$,

6) $H(ia - 1 : (i + 1)a - 2, \ \tau + (i - 1)a : \tau + ia - 1) = Z_2, \ \forall i \in [2 : \ell]$.

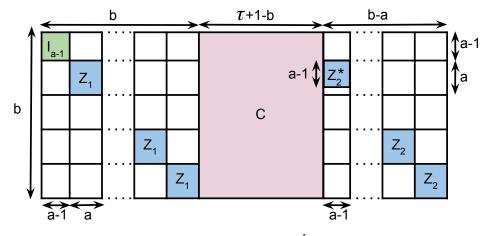

Fig. 5: P-C matrix of $\mathbb{C}_{a,b,\tau+1}^I$

1) An example: $\{a = 2, b = 5, \tau = 7\}$

The $\mathbb{C}_{2,5,8}^I$ is a $[n = 11, \ k = 6]$ code with p-c matrix,

$$H = \begin{bmatrix} 1 & 0 & 0 & 0 & 0 & c_{00} & c_{01} & c_{02} & 0 & 0 & 0 \\ 0 & z_{00} & 0 & 0 & 0 & c_{10} & c_{11} & c_{12} & z_{02} & 0 & 0 \\ 0 & z_{10} & z_{11} & 0 & 0 & c_{20} & c_{21} & c_{22} & 0 & 0 & 0 \\ 0 & 0 & 0 & z_{00} & 0 & c_{30} & c_{31} & c_{32} & 0 & z_{02} & z_{03} \\ 0 & 0 & 0 & z_{10} & z_{11} & c_{40} & c_{41} & c_{42} & 0 & 0 & z_{13} \end{bmatrix},$$

where $Z = \begin{bmatrix} z_{00} & 0 & z_{02} & z_{03} \\ z_{10} & z_{11} & 0 & z_{13} \end{bmatrix}$ is a 2×4 zero-band MDS generator matrix and $C = \begin{bmatrix} c_{00} & c_{10} & c_{20} & c_{30} & c_{40} & c_{5,0} \\ c_{01} & c_{11} & c_{21} & c_{31} & c_{41} & c_{5,1} \\ c_{02} & c_{12} & c_{22} & c_{32} & c_{42} & c_{5,2} \end{bmatrix}^T$

is a 5×3 Cauchy matrix.

Theorem V.3. *For any set of parameters* $\{a, b, \tau\}$ *such that* $\tau + 1 - a \geq b$ *and* $b \mod a = a - 1$ *, the DE of* $\mathbb{C}_{a,b,\tau+1}^I$ *results in a rate-optimal* (a, b, τ) *streaming code of field size* $O(\tau)$.

Proof: Let $b = \ell a + a - 1$.

1) For $i \in [0 : a - 2]$, consider the p-c matrix $H^{(0)} = H([0 : a - 2] \cup \{2a - 2\}, \ 0 : \tau)$. The columns of $H^{(0)}$ with index in $[2a - 1 : \ell a + a - 2]$ are all-zero. The submatrix is of the form shown below:

$$H^{(0)} = \left[\begin{array}{c|c|c} I_{a-1} & & C(0 : a - 2, 0 : \tau - b) \\ \hline Z_1(a - 1, 0 : a - 1) & 0_{a \times (\ell-1)a} & C(2a - 2, 0 : \tau - b) \end{array} \right]$$

Random Erasure Recovery: Fix some $i \in [0 : a-2]$ and let $A \subseteq [i : \tau] \setminus [2a-1 : \ell a+a-2]$ with $|A| \leq a$ such that $\underline{e}_i = \underline{h}_i^{(0)} = \sum_{j \in A \setminus \{i\}} u_j \underline{h}_j^{(0)}$, $u_j \in \mathbb{F}_q$. It can be easily seen that $u_j = 0$ for all $j \in A \cap ([i+1 : a-2] \cup [b : \tau])$ is necessary, as $\leq a - 1$ columns from $([i + 1 : a - 2] \cup [b : \tau])$ can not combine to form $\underline{e}_i$, because of MDS property. The remaining non-zero columns $[a - 1 : 2a - 2]$ of $H^{(0)}$ has support only in the last row and therefore cannot generate $\underline{e}_i$. Therefore it is possible to recover c_i from erasure given by A.

Burst Erasure Recovery: Again for a fixed $i \in [0 : a - 2]$, let $B = [i : i + b - 1]$. Since $\tau + 1 - b \geq a$, we have $\max(B) < \tau$. It can be also seen that $|B \cap ([i+1 : a-2] \cup [b : \tau])| = (a - 2 - i) + i = a - 2$ and $a - 2$

columns with index in $[i+1:a-2] \cup [b:\tau]$ can not linearly combine to form first $a-1$ rows of $\underline{e}_i$. Hence, burst erasure recovery condition is satisfied for $i \in [0:a-2]$.

2) For $i \in [ja-1:(j+1)a-2]$, where $j \in [1, \ell-2]$, consider the p-c matrix $H^{(ja-1)} = H([0:(j+1)a-2], 0: \tau + ja - 1)$. The columns of $H^{(j+a-1)}$ with index in $[(j+1)a-1:(\ell+1)a-2]$ are all-zero.
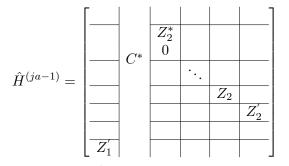

$$H^{(ja-1)} = \begin{bmatrix} \begin{matrix} I_{a-1} & & & \\ & Z_1 & & \\ & & \ddots & \\ & & & Z_1 \end{matrix} & 0 & C(0:(j+2)a-2, 0:\tau-b) & \begin{matrix} Z_2^* & & \\ 0 & & \\ & \ddots & \\ & & Z_2 \end{matrix} \end{bmatrix}$$

Random Erasure Recovery: Let $A \subseteq [i:i+\tau] \setminus [ja-1:(\ell+1)a-2]$ with $|A| \leq a$ and $i \in A$ be such that $\underline{h}_i^{(ja-1)} = \sum_{p \in A \setminus \{i\}} u_p \underline{h}_p^{(ja-1)}$, for some $u_p \in \mathbb{F}_q$. In $\underline{h}_i^{(ja-1)}$ the first $a-1$ rows are zeros and columns $[b:\tau]$ are the only columns in A with non-zero entries in first $a-1$ rows. Due to super-regular property of C, if one column from $[b:\tau]$ is part of the linear combination, then at least a columns from $[b:\tau]$ are needed to obtain zeros in first $a-1$ rows. Hence, we have $u_p = 0$ for all $p \in A \cap [b:\tau]$. Now, because to MDS property of Z, no collection of $a-1$ columns from $[i+1:(j+1)a-2] \cup [\tau+1:\tau+i]$ can span $\underline{h}_i^{(ja-1)}$. Hence, no such A exists and this proves random erasure recovery for c_i.

Burst Erasure Recovery: Now consider a burst erasure of length $\leq b$ starting at i, indexed by set $B = [i: i+b-1]$. Note that $|B \cap [b:\tau+b-a] = i$. If $i \leq \tau+1-b$, then the square submatrix formed by non-zero columns $H^{(ja-1)}$ with index in B is given by:

$$\hat{H} = \left[\begin{array}{c|c} 0 & C(0:i-1, 0:i-1) \\ \hline Z_1(i-ja+1:a-1, i-ja+1:a-1) & C(i:(j+1)a-2, 0:i-1) \end{array} \right],$$

which is clearly invertible because $C(0:i-1, 0:i-1)$ and $Z_1(i-:ja-1, i-ja+1:a-1)$ are non-singular. Now suppose $i > \tau+1-b$. The square submatrix formed by non-zero columns $H^{((j+1)a-1)}$ with index in B has the form:

$$\hat{H}^{(ja-1)} = \begin{bmatrix} & & \begin{matrix} Z_2^* \\ 0 \end{matrix} & & \\ & C^* & & & \\ & & \ddots & & \\ & & & Z_2 & \\ & & & & Z_2' \\ Z_1' & & & & \end{bmatrix}$$

where $C^* = C(0:(j+1)a-2, 0:\tau-b)$, Z_1' is a invertible submatrix of Z_1 and Z_2' is a invertible submatrix of Z_2. It can be shown that the number of rows of $\hat{H}^{(ja-1)}$ with support only in Cauchy part is $\tau - b$ and the submatrix of C with only these rows is invertible. The condition $\tau+1-b \geq a$ ensures that no row contains non-zero entries from both Z_1' and Z_2'. The invertibility of $\hat{H}^{(ja-1)}$ follows.

3) For $i \in [(\ell-1)a+a-1:\tau+b-a]$, the entire codeword is available for recovery of c_i.

$$H(0:b-1, (\ell-1)a+a-1:\tau+b-a) = \begin{bmatrix} & & \begin{matrix} Z_2^* \\ 0 \end{matrix} & & \\ & C & & & \\ & & & Z_2 & \\ & & & \ddots & \\ Z_1 & & & & Z_2 \end{bmatrix}$$

Random Erasure Recovery: Suppose there exists an $A \subseteq [(\ell-1)a + a - 1 : \tau + b - a]$ such that $|A| \leq a$ and $\sum_{j \in A} u_j \underline{h}_j = 0$, $u_j \in \mathbb{F}_q$. The Cauchy columns are the only columns with non-zero support in rows $[0, a-2] \cup 2a - 2$. No collection of $\leq a$ columns from Cauchy part can combine to form these a zeros, hence $A \cap [b : \tau] = \phi$. Now due to MDS property of Z and the support structure, it is not possible for $\leq a$ columns from the remaining part to be linearly dependent. Hence, no such A exists.

Burst Erasure Recovery: Consider any submatrix $\hat{H}$ formed by b consecutive columns of $H(0 : b - 1, (\ell - 1)a + a - 1 : \tau + b - a)$. It can be seen that the submatrix of $\hat{H}$ formed by Cauchy columns and rows where non-cauchy columns have no support is square and hence invertible. The condition $\tau + 1 - b \geq a$ ensures that more than a columns containing entries from same Z matrix are not part of $\hat{H}$. Now, it can be easily argued that $\hat{H}$ is invertible using support structure of $\hat{H}$ and properties of Z.
