## ABSTRACT

High-throughput screening techniques are commonly used to obtain large quantities of data in many fields of biology. It is well known that artifacts arising from variability in the technical execution of different experimental batches within such screens confound these observations and can lead to invalid biological conclusions. It is therefore necessary to account for these *batch effects* when analyzing outcomes. In this paper we describe *RxRx1*, a biological dataset designed specifically for the systematic study of batch effect correction methods. The dataset consists of 125,510 high-resolution fluorescence microscopy images of human cells under 1,138 genetic perturbations in 51 experimental batches across 4 cell types. Visual inspection of the images alone clearly demonstrates significant batch effects. We propose a classification task designed to evaluate the effectiveness of experimental batch correction methods on these images and examine the performance of a number of correction methods on this task. Our goal in releasing RxRx1 is to encourage the development of effective experimental batch correction methods that generalize well to unseen experimental batches. The dataset can be downloaded at <https://rxrx.ai>.

## 1 Introduction

High-throughput screening is commonly used in many biological fields, including genetics [1, 2] and drug discovery [3, 4, 5, 6]. Such screens are capable of generating large amounts of data that, when coupled with modern machine learning methods, could help answer fundamental questions in biology and solve the problem of rising costs in drug discovery, which are now estimated to be over 2 billion per approved drug [7, 8]. However, creating large volumes of biological data necessarily requires the data to be generated in multiple experimental batches, or groups of experiments executed at different times under similar conditions. Even when experiments are carefully designed to control for technical variables such as temperature, humidity, and reagent concentration, the measurements taken from these screens are confounded by artifacts that arise from differences in the technical execution of each batch. Figure 1c demonstrates the complexity of identifying relevant biological variation and separating it from technical noise caused by these so-called *batch effects*. Even when experiments are designed to control for technical variables such as temperature, humidity, and reagent concentration, batch effects unavoidably enter into the data. Batch effects can alter factors of variation within the images that are irrelevant to the biological variables under study but are unfortunately often correlated with them. It is therefore necessary to correct for such effects before drawing any biological conclusions [9, 10, 11, 12]. Indeed, many computational methods have been designed for correcting such effects [13, 14, 15, 16, 17, 18, 19, 20].

## RxRx1: A Dataset for Evaluating Experimental Batch Correction Methods

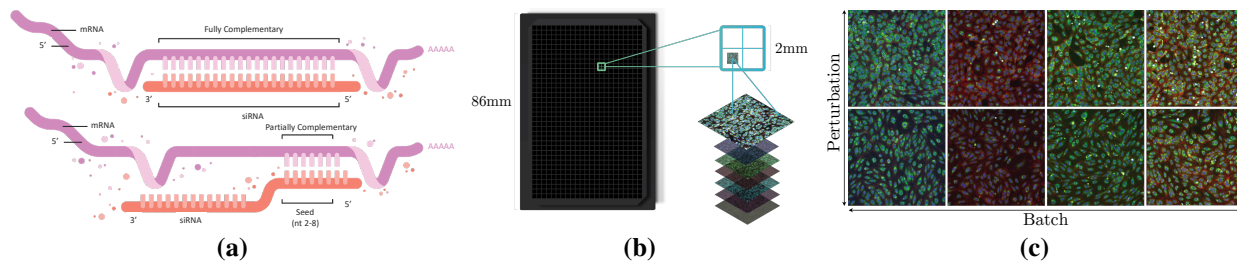

Figure 1: **(a)** Top: Depiction of full-complementarity of an siRNA to an mRNA to knockdown a particular target gene. Bottom: Depiction of partial-complementarity in the seed-region of an siRNA, leading to partial knockdown of hundreds of additional genes. **(b)** Schematic of a 384-well plate demonstrating imaging sites and 6-channel images. The experiments in this dataset were run in such plates. RxRx1 contains two 6-channel images from different sites per well. **(c)** Images of two different genetic conditions (rows) in HUVEC cells across four experimental batches (columns). Notice the visual similarity of images from the same batch.

In this paper, we describe the *RxRx1* dataset, an image dataset systematically designed to study batch effect correction methods. The dataset consists of 125,510 6-channel fluorescence microscopy images of human cells under 1,108 different genetic perturbations (plus 30 positive control perturbations) across 51 experimental batches and 4 cell types. We propose an invariant risk minimization task [21] to gauge the effectiveness of batch effect correction methods, namely learning to classify the genetic perturbation present in each image in a set of experimental batches held out from a training set. In order for a classifier to perform well on this task, it must be able to robustly identify the discriminative morphological features associated with each genetic perturbation against a background of the latent technical variations associated with each held-out experimental batch.

In the present article, we make three main contributions:

1. We present a dataset (46GB, 125,510 images, 1,139 classes including one EMPTY class) for testing experimental batch effect correction, comparable in size to reference datasets such as ImageNet [22] (155 GB, 1.2M images, 1000 classes) and other biological datasets like BBBC017 (56 GB, 64.5K images, 4903 classes) [23].
2. We introduce a specific task for evaluating the effectiveness of batch effect correction methods, accompanied by three evaluation metrics enabling users of this dataset to assess their developed methods.
3. We demonstrate the use of a standard convolutional classifier architecture as a backbone for the task of experimental batch correction and analyze the performance of variations of this model on such task.

This dataset and task will be of interest to the community of researchers applying machine learning methods to complex biological datasets, especially those working with image-based high-content phenotypic screens [24, 25, 26, 27, 28, 29]. In addition, we believe RxRx1 will be of interest to the larger community of machine learning researchers working in the areas of domain adaptation, transfer learning, and few-shot learning.

Figure 2: 6-channel faux-colored composite image of HUVEC cells (left) and individual channels (right) stained with Hoechst 33342 (channel 1, blue), Alexa Fluor 488 Concanavalin A (channel 2, green), Alexa Fluor 568 Phalloidin (channel 3, red), Syto14 (channel 4, cyan), MitoTracker Deep Red FM (channel 5, magenta), and Alexa Fluor 555 Agglutinin (channel 6, yellow). The similarity in content between some channels is due in part to the spectral overlap between the fluorescent stains used in those channels.

Figure 3: Images of 5 siRNA phenotypes in HUVEC cells across 5 experimental batches. Each siRNA causes changes in the visual properties of cell populations, including morphology, count, and spatial distribution.

## 2 Dataset

All images in RxRx1 were generated using Recursion’s high-throughput screening platform <sup>2</sup>. The dataset is comprised of fluorescence microscopy images of human cells of four different types:

- HUVEC: primary endothelial cells derived from the umbilical vein [30].
- RPE: epithelial cells from the outermost layer of the retina [31].
- HepG2: nontumorigenic cells with high proliferation rates and an epithelial-like morphology important for hepatic functions [32].
- U2OS: immortalized epithelial cells derived in 1964 from an osteosarcoma patient [33].

These were acquired using a proprietary implementation of the Cell Painting imaging protocol [34]. In Figure 2, we show an example image. Each channel corresponds to a fluorescent dye used to stain one of six different targeted cellular components, namely nuclei, endoplasmic reticuli, actin, nucleoli, mitochondria, and Golgi. The images themselves are the result of executing the same experimental design in 51 different experimental batches, with each execution separated by at least a week from all others. The experiment design consists of four 384-well plates (see Figure 1b), where each well contains an isolated population of cells. The wells are laid out on each plate in a  $16 \times 24$  grid, but only the wells in the inner  $14 \times 22$  grid are used since the outer wells are most susceptible to environmental factors. In each well, cell populations are genetically perturbed with small interfering ribonucleic acid, or siRNA, at a fixed concentration. Each siRNA is designed to knockdown a single target gene via the RNA interference pathway, reducing the expression of that gene [35]. In addition, siRNAs are known to have significant but consistent off-target effects via the microRNA pathway, creating partial knockdown of many other genes as well (see Figure 1a). Each siRNA, therefore, perturbs cellular function in a way that can impact visible properties of the cell population, including morphology, count, and spatial distribution (see Figure 3). The set of consistent, observable characteristics associated with each siRNA is called its *phenotype*. Note that the phenotype of an siRNA is sometimes visually distinct, but more often its visual characteristics are subtle and hard to detect by eye (see Figure 4).

### 2.1 Experiment design

Of the 308 usable wells on each plate, one is left untreated to provide a negative control (labeled EMPTY), and another 30 wells receive a unique siRNA from a positive control set of 30 siRNA. The remaining 277 wells receive a

<sup>2</sup><https://recursion.com>

Figure 4: Top row: Images of HUVEC cells under four different siRNA perturbations, all from the same plate. Bottom row: Images of cells under the same siRNA perturbation in four cell types: HUVEC, RPE, HepG2, and U2OS.

unique siRNA from a treatment set of 1,108 siRNA. Therefore, each 4-plate experiment contains 1,138 unique siRNA perturbations, where the positive and negative controls appear once on each plate, and the 1,108 treatments appear once in each 4-plate experiment. The location of each siRNA is randomized per experiment and plate, though for operational reasons, the 1,108 treatment siRNA are divided into four groups of 277 that always appear together on a plate. Note that some wells do not receive their intended siRNA (and are thus labeled EMPTY) due to detected operational errors, while images of occasional other wells are removed from the dataset due to detected poor image quality.

## 2.2 Image resolution

Images were acquired at a spatial resolution of  $2048 \times 2048$  and 16 bits per pixel (bpp) per channel, downsampled to  $1024 \times 1024$  at 8bpp, and cropped to the center  $512 \times 512$  field of view. RxRx1 contains two non-overlapping  $512 \times 512$  fields of view per well. Of the possible 125,564 total images ( $51 \text{ experiments} \times 4 \text{ plates/experiment} \times 308 \text{ wells/plate} \times 2 \text{ images/well}$ ), 154 images were excluded for failing quality filters, resulting in a total of 125,510 6-channel images in the dataset.

## 2.3 Cell types

The 51 experiments are distributed across four cell types: 24 in HUVEC, 11 in RPE, 11 in HepG2, and 5 in U2OS. Figure 4 shows the phenotype of a single siRNA in the four different cell types. Each of the 51 experiments was run in a different batch, resulting in images that exhibit distinct batch effects. It is this feature of the dataset that makes it particularly suited for studying batch effects and methods for correcting them.

## 2.4 Metadata

The following metadata is provided for each image in RxRx1: cell type, experiment id, plate id, well location, and treatment class (1,138 siRNA classes plus one untreated class).

## 3 Evaluation task

We propose the following invariant risk minimization task for evaluating the effectiveness of batch effect correction methods: learn to classify the genetic perturbation present in each image in a set of experimental batches held out from a training set. In order for a classifier to perform well on this task, it must be able to robustly identify the visual characteristics associated with each genetic perturbation against a background of latent, technical variations associated with each experimental batch.

### 3.1 Batch-separated vs batch-stratified splits

In order to appropriately evaluate such classifiers, we propose two strategies for splitting the data into training and test sets as well as two specific instantiations of these splits. The first, called the *batch-separated* split, assigns 33 of the 51

Figure 5: A diagram of our models. 6-channel images are fed to the backbone (DenseNet161 [36]). Feature maps from the backbone are pooled by global average pooling and then mapped by two fully connected layers, which follow batch normalization and ReLU layers to obtain a 1024-dimensional image embedding. The embedding layer is connected to two parallel branches – one for perturbation classification and the other for experimental batch classification. The experimental batch classification branch is either detached (for baseline and AdaBN model) or gradient reversed (for gradient reversal model). For both classification targets, we use cross-entropy loss.

experiments (16 HUVEC, 7 RPE, 7 HepG2, 3 U2OS) to the training set, and the remaining 18 (8 HUVEC, 5 RPE, 5 HepG2, 2 U2OS) to the test set. In this way, the experimental batches that make up the test set are different from those in the training set, which allows for assessing out-of-domain generalization. Note that this split is naturally stratified with respect to treatment class (see Section 2.1). The second split, called the *batch-stratified* split, stratifies the data by both treatment class and experimental batch. The size of the training and test sets are made roughly the same as in the batch-separated split. In the batch-stratified split, the training and test sets contain images from all experimental batches, making the classification task easier to learn since no experimental batch is out-of-domain. As a result, accuracy on the batch-stratified split provides an upper bound for accuracy on the batch-separated split, and we will use both of these numbers when evaluating experimental batch correction methods. Splits can be downloaded at <https://rxrx.ai>.

## 3.2 Evaluation metrics

With the batch-separated and batch-stratified splits defined, we now propose three evaluation metrics for assessing the effectiveness of experimental batch correction methods.

### 3.2.1 Perturbation classification accuracy

This metric is the average perturbation class classification accuracy (including controls and untreated as classes) on the test set when using the batch-separated split. It is useful as an overall measure of the goodness of the batch effect correction method since the test set contains experimental batches not seen during training and the training and test sets are stratified by siRNA classes.

### 3.2.2 Batch generalization

To define a metric that measures generalization to new experimental batches, we calculate perturbation classification accuracy using both the batch-separated and batch-stratified splits, and then measure the difference between these accuracies as follows:

$$\text{Generalization} = \frac{\text{SeparatedPertAcc}}{\text{StratifiedPertAcc}}$$

where *SeparatedPertAcc* is perturbation classification accuracy on the test set of the batch-separated split (after training on the batch-separated training set), and *StratifiedPertAcc* is perturbation classification accuracy on the test set of the batch-stratified split (after training on batch-stratified training set). A generalization of 100% means that perturbation classification accuracy on both splits is the same, *i.e.*, the experimental batch correction method has learned to classify perturbations in unseen experimental batches as well as it has learned to classify perturbations in seen experiment batches.

### 3.2.3 Batch classification accuracy

To measure whether image embeddings are batch-invariant, we train a separate head atop the embeddings to classify which batch each example is from. We use the batch-stratified split since the training data must contain examples from all batches. Except for later gradient reversal experiments, we do not backpropagate this separate head’s loss to the network trunk, so it serves as a simple probe to measure how much batch information is present in the embeddings. We generally want embeddings to be batch-invariant, *i.e.* batch classification accuracy at chance levels of  $1/51 \approx 1.96\%$ .

## 4 Experimental batch correction methods

In this section, we describe the methods for experimental batch correction that will be evaluated in this paper using the metrics defined in Section 3.2.

### 4.1 Baseline

The baseline method is a standard convolutional classifier architecture (see Figure 5). A detached batch classification head is added to calculate experimental batch accuracy without backpropagating experimental batch classification error into the rest of the network. For data augmentations, we use horizontal and vertical flips, 90-degree rotations, and CutMix [37]. We train for 100 epochs, using a cosine learning rate schedule with a 5 epoch linear warmup and learning rate of 0.1024, an SGD optimizer with 0.9 momentum, and a batch size of 512 distributed across 8 Nvidia A100 GPUs. Before feeding an image into the network, we preprocess the image with a channel-wise *self-standardization*, i.e., we subtract the mean and divide it by the standard deviation of the image’s pixel intensities per channel.

### 4.2 AdaBN

Adaptive batch normalization (AdaBN) [38] modifies standard batch normalization [39] layers to use statistics from individual domain distributions (e.g., from experimental batch distributions in our case) rather than the entire dataset distribution, both during training and at test time. Therefore, during training, it is necessary to sample mini-batches from a single experimental batch at a time. By doing so, the model is able to normalize intermediate features within the context of the experimental batch distribution. The rest of the model is unchanged (see Figure 5).

### 4.3 Gradient reversal

Gradient reversal [40] is an adversarial method that changes the sign of the gradient for specific layers in the model, e.g., layers connecting the heads of adversarial losses to the rest of the network. Intuitively, this method updates model weights at the gradient reversal layer in order to increase the adversarial loss, while the rest of the head updates its weights in order to decrease the loss, giving rise to the adversarial nature of this method. We want the model to be invariant to differences in experimental batches, thus to implement this method, we reattach the experimental batch classification head mentioned in Section 3.2.3 using gradient reversal (see Figure 5).

### 4.4 AdaBN + gradient reversal

We also apply adaptive batch normalization and gradient reversal simultaneously in order to evaluate their combined ability to correct experimental batch effects.

## 5 Experiments

In this section, we evaluate the methods described in Section 4 using the evaluation metrics described in Section 3.2.

### 5.1 Evaluation metric performance

Method	Perturbation classification accuracy (batch-separated)	Perturbation classification accuracy (batch-stratified)	Batch generalization	Batch classification accuracy
Baseline	75.1% $\pm$ 0.2%	<b>91.1%</b> $\pm$ 0.1%	82.4%	59.2% $\pm$ 0.7%
Gradient Reversal	71.2% $\pm$ 0.4%	89.1% $\pm$ 0.1%	79.9%	<b>1.8%</b> $\pm$ 0.1%
AdaBN	<b>87.1%</b> $\pm$ 0.2%	<b>91.1%</b> $\pm$ 0.1%	<b>95.6%</b>	16.4% $\pm$ 0.3%
AdaBN + Grad. Rev.	86.2% $\pm$ 0.3%	90.2% $\pm$ 0.2%	<b>95.6%</b>	2.3% $\pm$ 0.1%

Table 1: Performance of experimental batch correction methods on the proposed metrics. All models, despite having similar perturbation accuracy on batches seen during training, vary in their ability to generalize to new batches as well as batch classification accuracy. AdaBN improves generalization to new batches significantly, and gradient reversal reduces batch information encoded in embeddings. Using both methods simultaneously yields the benefits of both. For every method, the model was trained 5 times on both batch-separated and batch-stratified splits. For descriptions of the splits, metrics, and methods, see Sections 3.1, 3.2, and 4, respectively.

Figure 6: UMAP visualization of embedding spaces for baseline, gradient reversal, and AdaBN methods (AdaBN + gradient reversal UMAP is similar to AdaBN UMAP). Points represent embeddings of individual images in HUVEC experiment batches from the test set and are colored by the experimental batch (other cell types exhibit similar behavior). Note that while gradient reversal is able to reduce experimental batch classification accuracy to random when trained on the batch-stratified split, this behavior does not generalize well to unseen experimental batches. In contrast, AdaBN is far more effective in aligning unseen experiment batches.

The results of the experimental batch correction methods are summarized in Table 1. The baseline classifier generalizes poorly to new batches, classifying experimental batches about 30x better than random. The AdaBN model improves experimental batch generalization to nearly 96% while significantly reducing experimental batch classification accuracy ( $\sim 8x$  better than random). Interestingly, gradient reversal does not improve experimental batch generalization but does reduce experimental batch classification accuracy to random chance. Finally, combining AdaBN and gradient reversal yields the benefits of both methods: top experimental batch generalization and near-random experimental batch classification.

## 5.2 Visualization of embedding space

In order to gain a better understanding of the information encoded in the embeddings learned by each experimental batch correction method, in Figure 6 we visualize the learned embedding spaces from our baseline, gradient reversal, and AdaBN methods using UMAP embeddings [41]. We note that AdaBN + gradient reversal UMAPs are similar to AdaBN UMAPs. While gradient reversal is able to reduce experimental batch classification accuracy to random when trained on the batch-stratified split, this behavior does not generalize well to experimental batches from unseen experiment batches. In contrast, AdaBN is far more effective in aligning unseen experiment batches since it normalizes intermediate image features with the statistics of the associated experimental batch, rather than the statistics of the training set in standard batch normalization.

## 5.3 Effect of data augmentation and backbone choices

In Table 2 we present perturbation classification accuracy results for different choices of data augmentation methods and convolutional backbones. We note how shallower networks have worse performance, and how AdaBN boosts

Model	Baseline	AdaBN
Default	75.2	87.1
-CutMix	70.8	80.2
-CutMix +MixUp	75.6	83.9
backbone=resnet50	71.7	83.9
backbone=resnet101	71.9	84.6
backbone=densenet121	74.3	85.9

Table 2: Perturbation classification accuracy (%) for various choices of data augmentation methods and convolutional backbones of the baseline and AdaBN methods.

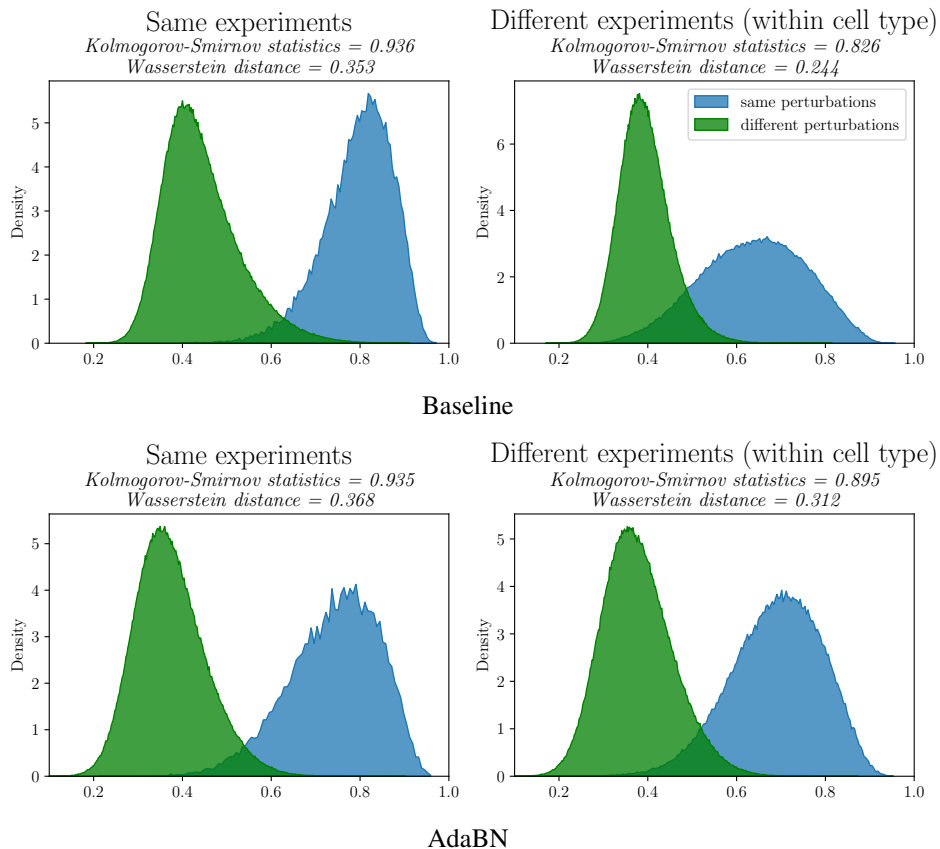

Figure 7: Distributions of cosine similarities between image embeddings for the baseline (**Top**) and AdaBN methods (**Bottom**). **Green**: cosine similarities between different perturbations. **Blue**: cosine similarities between the same perturbations. **Left**: cosine similarities between perturbations in the same experimental batches. **Right**: cosine similarities between perturbations in different experimental batches but the same cell type. Two measures of distributional similarity, KS statistic, and Wasserstein distance, are computed between the two distributions in each plot. Note that the baseline distributions of the same and different perturbation cosine similarities are distinctly different within and across experimental batches, while the AdaBN distributions are very similar, showing that AdaBN preserves geometric relationships between embeddings even across experimental batches. Note that cosine similarities are always positive because all values in embeddings are positive as embeddings are obtained by passing features through ReLU in the model.

accuracy over the baseline in all scenarios. We also note how using MixUp instead of CutMix augmentation gives better performance for the baseline but not AdaBN.

#### 5.4 Preservation of embedding similarities

While the previous section demonstrated that AdaBN is sufficient to align embedding distributions across experimental batches, we also wondered if it would preserve geometric relationships across batches. In order to answer this question, we consider the following distributions of cosine similarities between perturbation embeddings:

1. same perturbations in same experimental batches
2. different perturbations in the same experimental batches
3. same perturbations in different experimental batches (but same cell type)
4. different perturbations in different experimental batches (but same cell type)

In Figure 7, we compare distributions 1 and 2 with distributions 3 and 4, for both the baseline and AdaBN methods. The similarity of these pairs of distributions to each other would be strong evidence that the experimental batch correction method preserves geometric relationships across experimental batches. Moreover, we calculate two measures of

Model	HUVEC	RPE	HepG2	U2OS
Baseline	84.2 $\pm 0.2$	79.0 $\pm 0.4$	76.2 $\pm 0.1$	26.1 $\pm 1.5$
Gradient reversal	83.8 $\pm 0.2$	78.1 $\pm 0.5$	74.0 $\pm 0.6$	24.3 $\pm 0.7$
AdaBN	<b>92.1</b> $\pm 0.2$	87.2 $\pm 0.0$	<b>86.2</b> $\pm 0.2$	<b>68.2</b> $\pm 0.1$
AdaBN + gradient reversal	92.0 $\pm 0.0$	<b>87.5</b> $\pm 0.1$	85.6 $\pm 0.1$	66.9 $\pm 0.3$

Table 3: Perturbation classification accuracy (%) per cell type. Note that increases in perturbation classification accuracy due to AdaBN are larger for more difficult cell types.

Model	HUVEC	RPE	HepG2	U2OS
Baseline	39.5 $\pm 0.7$	39.2 $\pm 2.0$	31.4 $\pm 0.4$	2.8 $\pm 1.0$
Gradient reversal	41.4 $\pm 0.5$	38.8 $\pm 0.5$	32.3 $\pm 0.4$	3.0 $\pm 0.3$
AdaBN	55.1 $\pm 1.1$	56.1 $\pm 0.4$	<b>56.2</b> $\pm 1.6$	44.0 $\pm 0.9$
AdaBN + gradient reversal	<b>55.3</b> $\pm 2.0$	<b>56.7</b> $\pm 0.9$	55.5 $\pm 0.6$	<b>44.1</b> $\pm 1.4$

Table 4: Perturbation classification accuracy (%) per cell type on simplified training sets containing only 3 experiments of a single cell type. HUVEC, RPE, and HepG2 cell types are easier to learn than U2OS, however, AdaBN significantly improves all classification accuracies, especially U2OS.

distributional similarity, KS statistic and Wasserstein distance, between each pair of distributions in order to quantify these similarities. As can be seen, the baseline distributions of the same and different perturbation cosine similarities are distinctly different within and across experimental batches, indicating that geometric relationships are not preserved across experimental batches for the baseline method. In contrast, the AdaBN distributions are very similar within and across experiment batches, demonstrating that AdaBN does indeed preserve geometric relationships across experimental batches.

## 5.5 Classification accuracy per cell type

Table 3 shows perturbation classification accuracy for each of the four cell types. Note that HUVEC accuracies are highest, followed by RPE and HepG2, and finally U2OS. This is in line with the differing proportions of experimental batches per each cell type in the training set. In order to obtain a more fair comparison of per-cell perturbation classification accuracy, we randomly selected 3 experimental batches for each cell type from the original training set to form a new training set. The results are shown in Table 4. We note that the HUVEC, RPE, and HepG2 cell types are far easier to learn than U2OS; however, AdaBN significantly improves classification accuracies in all cell types, especially U2OS. Comparing the results (for U2OS since training sets were the same in both) in Tables 3 and 4, we conclude that jointly training a method on all cell types rather than individual cell types greatly improves perturbation classification accuracy.

## 5.6 Channel importance

In Figure 8, we study the importance of each channel by plotting its Shapley value [42] for the baseline method. Shapley values measure the relative contributions each channel makes when assigning correct classes to our (batch-separated) test set. Channels 2 and 4 are most important, while Channel 6 is the least important. We note that the large importance of Channels 2 and 4 is likely due to the spectral overlap that their fluorescent stains have with the stains of other channels in Recursion’s protocol, specifically Channel 1 (which consequently lowers the relative accuracy contribution of Channel 1). In Figure 9 we show perturbation classification accuracy of the baseline method trained on all non-empty subsets of channels. Interestingly, we observe that the model that uses all 6 channels does not yield the best performance. All channel subsets containing at least 4 channels without Channel 6 surpass the all-channels baseline. Using all but Channel 6 exceeds the baseline by 2 percentage points. We hypothesize that this observation is a result of overfitting the model on RxBx1 with its particular channel statistics, not that models with fewer input channels will in general outperform models with access to all input channels.

Figure 8: The Shapley values for each channel using the baseline method, represent contributions to perturbation classification accuracy. Higher values represent greater importance. Similar Shapley values are observed for each experimental batch correction method.

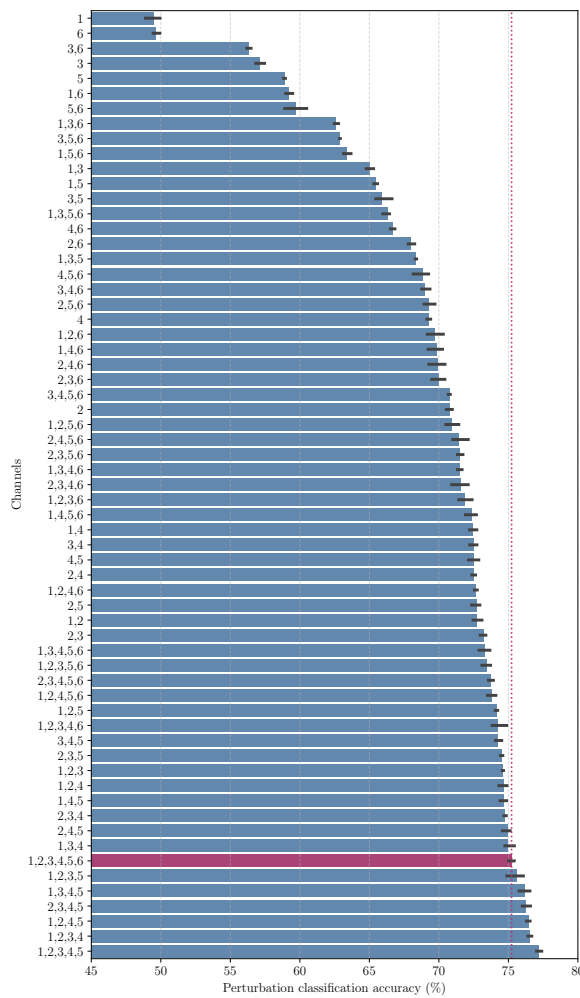

Figure 9: Perturbation classification accuracy of baseline method trained on different subsets of channels.

### 5.7 Image preprocessing

We tried different image normalization methods for preprocessing the images. In all cases, we calculate per-channel means and standard deviations on different subsets of the dataset and standardize each image with those statistics (*i.e.*, subtract the mean and divide by the standard deviation) before using them as input to the networks. The (batch-

Normalization	Accuracy
All images	60.8 $\pm$ 1.1
Control images per experiment	68.4 $\pm$ 0.5
All images per experiment	68.6 $\pm$ 0.5
Control images per plate	73.4 $\pm$ 0.3
All images per plate	73.4 $\pm$ 0.5
Self-standardization	<b>75.1 <math>\pm</math> 0.2</b>

Table 5: Perturbation classification accuracy (%) for different image normalization methods on the batch-separated split using the baseline method. Self-standardization, where each channel of a single image is standardized by its own mean and standard deviation, yields the best results.

Normalization	Accuracy
All images	78.4
Control images per experiment	83.6
All images per experiment	83.7
Control images per plate	81.7
All images per plate	82.6
Self-standardization	<b>87.1</b>

Table 6: Perturbation classification accuracy (%) for different image normalization methods using AdaBN.

separated) perturbation classification accuracies associated with each normalization method are presented in Table 5. Self-standardization (standardization using only the image itself) outperforms other methods by a significant margin. Interestingly, the self-standardization improves perturbation classification accuracy by more than 14 percentage points compared to the common computer vision practice of using global statistics calculated from the entire training set. We hypothesize that this margin is due to the uniform background of RxRx1 images across experimental batches, which contains little biological information but whose size relative to the foreground of cells can change dramatically from perturbation to perturbation and even image to image. Thus image-level statistics are proportional to the cellular content of an image, so that self-standardization normalizes each image to the common scale of the average cell contained within the image.

In Table 6 we show perturbation classification accuracy for different image normalization methods using our AdaBN method. Similar to Table 4, self-standardization (*i.e.*, per-image statistics) offers the best perturbation classification accuracy.

## 5.8 Training dynamics

In Figure 10, we plot test perturbation classification accuracy means and standard deviations during model training (over 5 runs). Our results show that the model architecture with AdaBN converges faster than the baseline. Moreover, AdaBN has a much smaller standard deviation than the baseline, *i. e.*, the each run is more consistent with the others for AdaBN.

## 6 Conclusion

In this paper, we described the *RxRx1* dataset, an image dataset systematically designed to study experimental batch effect correction methods. The dataset contains 125,510 6-channel, high-resolution fluorescence microscopy images of human cells under 1,138 genetic perturbations in 51 experimental batches across 4 cell types. We proposed a task and several metrics to evaluate the performance of different experimental batch correction methods. We demonstrated that while both adaptive batch normalization (AdaBN) [38] and gradient reversal [40] are effective techniques for removing experimental batch information from image embeddings, only AdaBN was effective in generalizing to unseen experimental batches, due to the manner in which it normalizes all intermediate feature maps using statistics from the corresponding experimental batch. We also demonstrated the importance of each image channel in this task, and the value of self-standardization as an image preprocessing step. We hope that the introduction of the *RxRx1* dataset will encourage further research into the complex problem of correcting experimental batch effect, as well as other issues that arise in the analysis of high-throughput screening data.

Figure 10: Test perturbation classification accuracy during model training (mean and standard deviation from 5 runs). AdaBN model converges faster, and the runs are more consistent with each other.

## 6.1 Future directions

There are several methodologies for extracting features from microscopy imaging screens, including manual feature extraction (e.g., using CellProfiler) [43, 44], leveraging pre-trained deep learning models [28, 45], and training deep learning models on microscopy images directly [46]. As both AdaBN and gradient reversal are deep learning methodologies, it is not possible to directly apply these methods to traditional feature extraction pipelines, yet an appropriate comparison would be useful to understand the benefit of end-to-end feature training.

Our approach relies on weakly supervised learning [47, 48] since we train models to predict the experimental perturbation in each well, without validating that each treatment induces a unique visual phenotype (N.B.: such validation is likely impossible). This means that there might be multiple perturbations which either do not perturb the cellular morphology or perturb it in similar ways to other perturbations, yet the perturbation classification task would reward distinguishing them. This would encourage reliance on spurious features or correlation, which inhibits learning image representations that capture meaningful morphological features and generalizing out of batch. Recently, self-supervised methods have been shown to match the performance of supervised models on natural image computer vision tasks [49, 50, 51]. Applying such training techniques for microscopy screening data [52, 53] represents a potentially fruitful direction for this work.

Finally, we acknowledge that the proposed perturbation classification task groups any morphological variation not associated with a common perturbation under the umbrella term *experimental batch effect*, which is usually reserved for technical effects only. One could imagine improving the task in a way that would not penalize intrinsic morphological features, like those associated with cell type differences, even if they are not associated with variations amongst perturbations. Such a task would promote the development of more effective experimental batch correction methods that better disentangle biological and technical causal factors, and we hope to provide such an update to this work in the future.
