Abstract

Efficient inference for object detection networks is a major challenge on edge devices. Post-Training Quantization (PTQ), which transforms a full-precision model into low bit-width directly, is an effective and convenient approach to reduce model inference complexity. But it suffers severe accuracy drop when applied to complex tasks such as object detection. PTQ optimizes the quantization parameters by different metrics to minimize the perturbation of quantization. The p -norm distance of feature maps before and after quantization, L_p , is widely used as the metric to evaluate perturbation. For the specialty of object detection network, we observe that the parameter p in L_p metric will significantly influence its quantization performance. We indicate that using a fixed hyper-parameter p does not achieve optimal quantization performance. To mitigate this problem, we propose a framework, DetPTQ, to assign different p values for quantizing different layers using an Object Detection Output Loss (ODOL), which represents the task loss of object detection. DetPTQ employs the ODOL-based adaptive L_p metric to select the optimal quantization parameters. Experiments show that our DetPTQ outperforms the state-of-the-art PTQ methods by a significant margin on both 2D and 3D object detectors. For example, we achieve 31.1/31.7(quantization/full-precision) mAP on RetinaNet-ResNet18 with 4-bit weight and 4-bit activation.

1. Introduction

Benefiting from the incredible power of deep learning, object detection networks [29, 22] have achieved eye-

popping performance. However, a large number of parameters and storage requirements present challenges for real-time inference when deployed on edge devices in the real world such as smartphones and electric cars. It is necessary to reduce the memory footprint and computational cost for efficient inference.

There are various methods for compressing Convolutional Neural Networks (CNNs) to improve inference efficiency, such as pruning [13], quantization [10], and knowledge distillation [11]. Among these methods, quantization is particularly promising as it converts full-precision (FP) values to integer grids, reducing computational burden. Quantization can be further divided into two types: Quantization-Aware Training (QAT)[8] and Post-Training Quantization (PTQ)[25]. Many researchers have retrained object detection networks using labeled training datasets for quantization (i.e., QAT) and achieved great performance. However, QAT can be hindered by the unavailability of labeled datasets due to privacy concerns and the time-consuming training process. PTQ, on the other hand, aims to quantize pre-trained models without retraining, only requiring a small un-labeled calibration dataset. It is popular for deployment in real-world applications.

Current PTQ methods mainly focus on image classification, with little exploration into their application in object detection. Object detection networks not only classify multiple objects but also regress the location offsets of bounding boxes. These networks have complex architectures, often containing multi-level and multi-dimensional outputs, as opposed to a single vector output in classification networks. These multi-level outputs detect objects of various scales. We observe that different detection levels have different sensitivities to quantization perturbation. When quantizing object detection networks, it suffers a significant performance drop, especially in extremely low-bit settings.

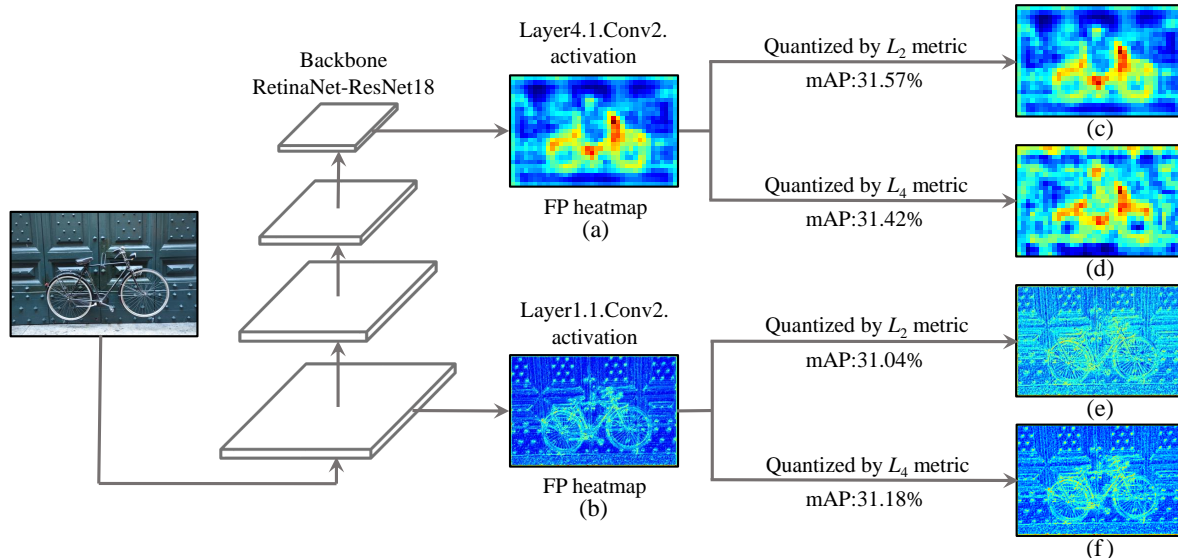

Figure 1: Visualization of the 4-bit PTQ on different activation layers using different L_p metrics in an object detection network (RetinaNet-ResNet18). All the mAP results are reported on the COCO validation set when quantizing only one activation layer of the network. (c), (d), (e) and (f) show the heatmap of the quantized activation.

The goal of quantization is to find the optimal quantization parameters that allow the quantized network to achieve the best task performance (minimizing the task loss or maximizing metrics such as mAP [23]). However, because labeled data is not available in PTQ, the network’s task performance cannot be directly evaluated. To approximate the task loss, previous PTQ methods [25, 20, 32] often optimize the quantization parameters layer-wise or block-wise to minimize the reconstruction loss for the output of the intermediate layers or blocks, known as local quantization reconstruction. They hypothesize that the block-wise (or layer-wise) optimization is mutual-independent and lack attention to the final task output. Those methods use a fixed metric to evaluate (such as L_2 loss) the intermediate feature maps before and after quantization. In this paper, we argue that *using a fixed metric without considering its sensitivity to task performance will negatively impact the quantization performance.*

In this paper, we find that the parameter p in the L_p metric has a significant impact on the quantization of object detection networks. We investigate the influence of different L_p metrics on quantization parameters which generated by local quantization reconstruction. We also visualize the quantized feature maps with different L_p metrics. Taking Figure 1 as an example, we observe that setting L_2 as quantization metric brings better task performance for the upper level feature map, while setting L_4 metric is more beneficial to the lower level feature map. This phenomenon is especially obvious in detection networks. We conclude that *different levels of feature maps require different L_p metrics*

to achieve better detection performance.

To determine the optimal p values for different levels of features, we propose DetPTQ to select the p value that makes the local L_p loss approximate to the final task loss. Because labeled data is not available in PTQ, we propose the Object Detection Output Loss (ODOL) which can represent the curve change of the task performance loss when quantizing the network. DetPTQ chooses the p value that makes the L_p loss approximate to the ODOL. To evaluate our method, we experiment on various architectures, including the one-stage 2D detection network RetinaNet [22], the two-stage 2D detection network Faster RCNN [29], and the point cloud 3D detection network PointPillar [18]. Our work makes the following contributions:

1. We indicate that local quantization reconstruction requires an adaptive loss metric for PTQ on object detection networks.
2. We propose a PTQ framework, DetPTQ, that assigns different L_p metric to quantize the different layers. We propose the ODOL, an approximation of the task loss, to model the global information.
3. Experiments on 2D and 3D object detectors show that DetPTQ outperforms the state-of-the-art PTQ methods. For example, DetPTQ achieves less than 1% mAP drop with 4-bit PTQ on all of the ResNet-based networks for the first time.

2. Related Work

2.1. Quantization-aware Training (QAT)

QAT [17, 5, 8] uses the entire training datasets to optimize the network for quantization. The quantization function quantizes tensors in forward-propagation, which has zero-gradient almost everywhere. QAT methods utilize the Straight Through Estimator (STE) [2] to avoid the zero-gradient problem. Recently, object detection quantization has attracted extensive attention for on-device deployment. [16] constrains the bitwidth of objection detection quantization to 8-bit (W8A8), and achieves good results on COCO dataset [23]. FQN [19] quantizes RetinaNet [22] and FasterRCNN [29] to 4-bit for the first time and demonstrates usable performance. AQD [4] pushes the limits of bit-width in object detection network quantization down to 2-bit. Although QAT methods achieve promising results in object detection, extensive training cost and the requirement of labeled datasets prevent its real-world deployment.

2.2. Post-training Quantization (PTQ)

Compared with QAT, PTQ [1, 33, 14] plays an important role in fast network deployment. AdaRound [25] minimizes the L_2 loss layer-wisely to optimize a rounding scheme and scale factors. Brecq [20] introduces block reconstruction to improve AdaRound. QDrop [32] shows decent performances at 2-bit by randomly dropping quantized activation during local reconstruction. PD-Quant [24] proposes the prediction difference loss (PD-loss) as an approximation of the task loss. PD-Quant only explores the metric to classification tasks and requires forward propagation to calculate PD-loss too many times. We explore the object-detection-based prediction difference loss. As the computation cost of object detection is much higher than classification, the adaptive local L_p loss in our DetPTQ can greatly reduce the quantization overhead.

Previous works explore the influence of metrics to measure the difference relative to the full-precision for PTQ. LAPQ [27] find that scale factors from different L_p metrics will cause different quantization errors. It adopts the Powell Algorithm to jointly optimize scale factors from different L_p metrics. PTQ4ViT [36] proposes to utilize a Hessian-guided metric to evaluate different scale factors for vision transformer. RAPQ [34] shows a theory that p value is positively correlated with the sensitivity of the L_p loss value to outliers. It takes the variance information from BN [15] to define a BN-based L_p loss. In our method, we use the global task information (i.e., ODOL) to set the p value.

Object detection networks often generate multi-level outputs or carry out feature fusion by FPN [21] to detect objects of different scales. Many PTQ methods such as Brecq and QDrop have successfully extended to objection detection networks but they do not consider the characteristics of

object detection networks. They use fixed loss in local reconstruction, which is sub-optimal. Because different levels have different sensitivities, we propose an adaptive loss in local reconstruction.

3. Preliminaries

The quantization function transforms a float-point value x to an integer value \tilde{x} , and x^q represents the dequantized float value with some error from x :

$$\tilde{x} = clip(\lfloor \frac{x}{s} \rfloor + z, n, m) \quad (1)$$

$$x^q = (\tilde{x} - z) \cdot s \quad (2)$$

where $\lfloor \cdot \rfloor$ means that the input $\frac{x}{s}$ is rounded to the nearest integers (i.e., rounding-to-nearest), which causes the rounding error Δr . $clip(\cdot)$ clips the values that lie outside of integer range $[n, m]$, which causes the clipping error Δc . \tilde{x} denotes the integer value, z is zero-point and s denotes the quantization scale factor. The total perturbation of quantization is $\Delta p = \Delta c + \Delta r = x - x^q$.

PTQ searches for the optimal quantization parameters by solving the problem of minimizing the local reconstruction loss:

$$\arg \min_s \|O - O^q\|_2 \quad (3)$$

where O denotes a FP tensor. O^q is the quantized tensor. $\|\cdot\|_2$ denotes the L_2 loss (MSE). For simplicity, we denote all of the quantization parameters with s . Previous PTQ methods [1, 6] sequentially search the quantization parameters s to minimize the local reconstruction loss layer-by-layer or block-by-block without any training or fine-tuning. This is referred to as the **simple PTQ method**.

Recently, some **advanced PTQ methods** have been proposed, such as AdaRound, BRECQ and QDrop, which reconstruct the weight for better quantization. They bring an extra variable v to each weight w and optimize the variable to minimize the local reconstruction loss of the output of a block. The quantization function and the optimization are formulated as:

$$\tilde{w} = clip(\lfloor \frac{w+v}{s} \rfloor + z, n, m), w^q = (\tilde{w} - z) \cdot s \quad (4)$$

$$\arg \min_{V,s} \|O - O^q\|_2 \quad (5)$$

where V is all of the extra variables in a block. Our method is orthogonal to the selection of simple PTQ and advanced PTQ, so we denote s as all of the quantization parameters including V for simplicity.

To analyze the influence of the metric for quantization perturbation, we replace the L_2 loss with the L_p loss (MSE can be regarded as a special case of $p = 2$). The local

reconstruction loss is changed to:

$$\|O - O^q\|_p = \left(\sum_i \|O_i - O_i^q\|_p\right)^{1/p} \quad (6)$$

RAPQ [34] has demonstrated that the p value of the L_p loss is positively correlated with the clipped range. For object detection networks, we also find that a larger p for L_p metric leads to a larger scale factor, and vice versa. Next, we will deeply explore the influence of different p values.

4. Method

4.1. Influence of Different p Values

The goal of quantization algorithm is to find the optimal quantization parameters to minimize the performance loss caused by the quantization perturbation. PTQ methods usually use MSE (L_2) to measure the difference before and after quantization to evaluate the performance loss. Since mean Average Precision (mAP) is the main evaluation metric for object detection task, the performance loss can be defined as

$$\mathcal{L}_{\text{perf}} = mAP^{fp} - mAP^q \quad (7)$$

where mAP^{fp} denotes the performance of the FP network on validation set, which is a constant value for a pre-trained model. mAP^q is the performance of the quantized network.

To investigate the influence of different p values of L_p metric on different layers, we compare the results of performance loss when quantizing only one layer of the network. In Table 1, we observe that the quantization parameters s are quite different using different p . There are also significant differences in performance losses. For Layer1.1.Conv2, we observe that the scale factor from L_3 has minimal performance loss (0.49), while the scale factor chosen by L_2 (MSE) metric is sub-optimal (performance loss is 0.66). As a hyper-parameter of L_p metric, the best p value is different for different layers. In this example, L_2 is the best for Layer4.1.Conv2, while L_3 is the best for Layer1.1.Conv2. Using a fixed L_p metric does not bring to the optimal quantization parameters. p values need to be adjusted for different layers or blocks.

The visualization plot of feature maps in Figure 1 demonstrates the influence of different p values. The output activation from Layer1.1.Conv2 is to detect small targets. From the heatmap (b) using L_2 , we can observe that the large activation values are clipped to the same value as small activations, causing the detector cannot distinguish the small objects. A larger p is better to get a larger scale factor s , reducing the clipping error on large activations. From the heatmap (b) using L_4 , the small objects can be distinguished. The results also show quantizing it using L_4 (31.18% mAP) is better than L_2 (31.04% mAP). Regarding the high-level activation Layer4.1.Conv2, it detects big

Metric	Layer1.1.Conv2		Layer4.1.Conv2	
	s	$\mathcal{L}_{\text{perf}}$	s	$\mathcal{L}_{\text{perf}}$
Min-Max	0.3472	6.00	0.5068	0.30
L_1	0.1076	2.14	0.2246	3.17
L_2	0.1885	0.63	0.3462	0.10
L_3	0.2102	0.45	0.4273	0.21
L_4	0.2695	0.49	0.4982	0.25

Table 1: Comparison of performance loss among different metrics for 4-bit quantization of RetinaNet-Resnet18. We only optimize the scale factor s of one layer’s output activation to minimize the local reconstruction error evaluated by L_p metrics. Min-Max is to set the scale factor s that covers all of the activation distribution.

targets and is more sensitive to global semantic information. The heatmap (c) illustrates that clipping large activation values by L_4 metric does not significantly affect the detection of big targets. It is more inclined to use a small p value for the L_p metric to achieve a higher mAP. We conclude that different level activations call for different L_p metrics to achieve accurate detection performance for PTQ. Choosing the right L_p metric to search for the optimal quantization parameters that lead to optimal performance loss is the key issue addressed in the following section.

4.2. Object Detection Output Loss (ODOL)

It is a challenge to select the p in L_p metric for local quantization reconstruction. Note that the goal of quantization algorithm is to find the optimal quantization parameters to minimize the performance loss $\mathcal{L}_{\text{perf}}$. Because the p value becomes a variable, the formulation of local reconstruction optimization is:

$$\arg \min_p \mathcal{L}_{\text{perf}}(s_p^*) \quad (8)$$

$$s_p^* = \arg \min_s \|O - O^q\|_p \quad (9)$$

where s_p^* is the optimal quantization parameters given p for local reconstruction and $\mathcal{L}_{\text{perf}}(s_p^*)$ is the performance loss with the quantized network using s_p^* . We denote s_{ideal}^* as the ideal quantization scaling factor, which leads to the lowest performance loss $\mathcal{L}_{\text{perf}}$ assuming we have the labeled data. However, there is no label for PTQ’s calibration data to calculate the mAP and the $\mathcal{L}_{\text{perf}}$. Next, we will propose the Object Detection Output Loss (ODOL) that measures the output difference between the quantized network and FP network as an approximation to $\mathcal{L}_{\text{perf}}$. We expect that the scale factor, which is optimized by the function, is consistent with s_{ideal}^* .

The output of object detection networks usually contains two parts: the score for classification and the offset for regression. For classification part, we calculate the distance

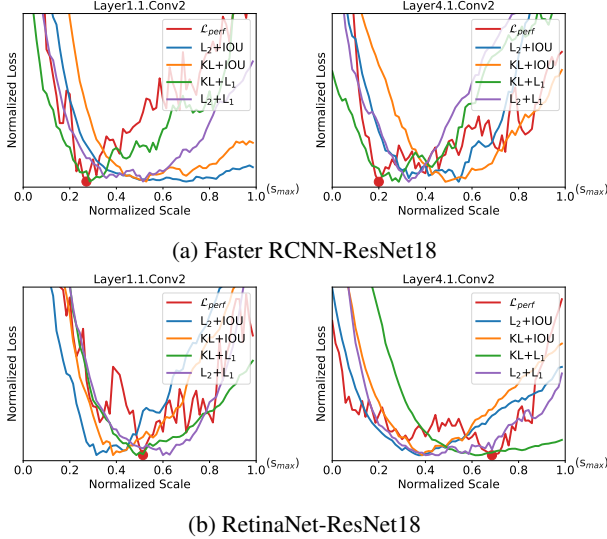

Figure 2: Quantization scale-loss curves with different loss functions. The scaling factor s_{max} is calculated by Min-Max quantization and then normalized to 1.0. The loss values (y-axis) are normalized for comparison.

of probabilities predicted by FP network and quantized network for **all boxes**, which is denoted as class loss \mathcal{L}_{cls} . For regression part, we calculate the coordinate distance of the boxes predicted by FP network and quantized network for **positive boxes**, which is denoted as localization loss \mathcal{L}_{loc} . The function expression of ODOL is formulated as following:

$$\mathcal{L}_{ODOL} = \frac{1}{N} \sum_{i=1}^N (\mathcal{L}_{cls,i} + \alpha \mathcal{L}_{loc,i} I_{pos,i}) \quad (10)$$

$$\mathcal{L}_{cls,i} = MSE(c_i, c_i^q) \quad or \quad KL(c_i, c_i^q) \quad (11)$$

$$\mathcal{L}_{loc,i} = L_1(l, l^q) \quad or \quad IOU(l, l^q) \quad (12)$$

where the $I_{pos,i}$ is the indicator of whether the i -th box is a positive box. N denotes the number of anchors. α is a balanced weight. c and l refer to FP output of scores and coordinates, while c^q and l^q are the output of scores and coordinates from the quantized network.

We explore various functions for ODOL. We attempt L_2 distance and KL distance to measure the classification difference \mathcal{L}_{cls} . For localization loss \mathcal{L}_{loc} , we attempt L_1 distance and IOU loss [35] to measure the distance of coordinate between the FP boxes and quantized boxes. To evaluate different loss functions, we compare different scale-loss curves in Figure 2. The red line is the performance loss, and

We filter all boxes by a threshold on the score from FP network and select the top 500 boxes. Then we perform NMS [28] on those k boxes to produce positive boxes and indicator $I_{pos,i}$. We decode the predicted offset to get the real coordinate for l and l^q .

the ideal scale s_{ideal}^* is located in the **red point**. We can observe that the scale factor optimized by ODOL with $KL+L_1$ (**green line**) is close to s_{ideal}^* . Taking an instance, when quantizing the activation of Retinanet-resnet18 Layer1.1.Conv2, s_{ideal}^* is around $0.48 \times s_{max}$, which is almost the same as ODOL with $KL+L_1$ optimized. We will show more experiment results for the different combinations of ODOL in Section 5.3. According to the experimental findings, we choose KL as the \mathcal{L}_{cls} and L_1 as the \mathcal{L}_{loc} as an approximation of \mathcal{L}_{perf} .

Algorithm 1 Network quantization using DetPTQ

Input: calibration dataset X^1 and a network with L blocks.
Output: quantization parameters of both activation and weight in network

- 1: input X^1 to FP network to get the FP output;
 - 2: **for** $B_i = \{B_i | i = 1, 2, \dots, L\}$ **do**
 - 3: Initialize a list D ;
 - 4: Input X^l from quantized block B_{i-1} to FP block B_i ;
 - 5: **for** $P = \{p_i | i = 1, 2, \dots, k\}$ **do**
 - 6: Optimize only activation quantization parameters to minimize Eq 14 in block B_i to get s_p^* ;
 - 7: Quantize activations in B_i to get O^q ;
 - 8: Input O^q to the following FP network to get output of partial-quantized network;
 - 9: Calculate $\mathcal{L}_{ODOL}(s_p^*)$ using Eq 10;
 - 10: Append $\mathcal{L}_{ODOL}(s_p^*)$ to list D ;
 - 11: **end for**
 - 12: $index \leftarrow argmin(D)$;
 - 13: $p^* \leftarrow P[index]$;
 - 14: Optimize quantization parameters for both activation and weight to minimize Eq 14 using p^* in block B_i ;
 - 15: Quantize weights and activations in B_i to get O^q ;
 - 16: O^q as the input X^{l+1} to next FP block B_{l+1} ;
 - 17: **end for**
-

4.3. DetPTQ Framework

One intuition is that we can use ODOL as a metric to directly optimize the quantization parameters to minimize the distance for the intermediate layer’s activation before and after quantization, just as PD-Quant [24] and NWQ [31] do. However the computation cost of object detection is very large. Repeated forward propagation to calculate ODOL is not realistic. In the section above, we observe that the parameter p in L_p metric has a significant influence on quantization. And we propose ODOL as an approximation of performance loss to determine p value for L_p metric. In this case, ODOL is computed as many times as the number of candidate p values. The local quantization reconstruction using ODOL can be formulated as:

$$\arg \min_p \mathcal{L}_{ODOL}(s_p^*) \quad (13)$$

Method	Bits(W/A)	Faster RCNN			RetinaNet		
		ResNet-18	ResNet-50	MobileNetV2	ResNet-18	ResNet-50	MobileNetV2
FP	32/32	34.23	38.46	29.91	31.67	37.38	28.40
MSE	4/8	31.02	35.35	19.02	28.64	34.88	9.85
Cosine	4/8	30.61	34.49	14.41	28.43	34.42	2.24

DetPTQ* (Ours)	4/8	32.96	37.04	19.96	28.95	36.51	12.42
MSE	4/4	27.75	29.10	8.04	24.81	30.31	2.74
Cosine	4/4	21.59	19.77	0.27	21.48	18.97	0.04
BN-based adaptive L_p	4/4	24.77	28.25	8.12	25.23	27.43	3.38
DetPTQ* (Ours)	4/4	30.04	31.18	9.87	27.67	32.13	5.65

Table 2: Comparison DetPTQ* with the simple PTQ method optimized by various metrics on COCO. W/A means the bit which weight/activation is quantized to.

$$s_p^* = \arg \min_s \|O - O^q\|_p \quad (14)$$

Next, we will propose our PTQ framework, DetPTQ. The same as previous methods, we quantize blocks in sequential order so that the perturbation accumulated in earlier blocks can be made up. When quantizing the l_{th} Block (B_l), the blocks before B_l have been quantized and the blocks after B_l are in floating-point.

As shown in Algorithm 1, the quantization process for a block includes two steps. The first step is to select the p value. Our experiments in Section 5.3 shows the quantization of weight is not sensitive to the selection of p . Therefore, we only use the scale factor for activation values to speedup the search of p . Given a set of values $P = \{p_i \mid i = 1, 2, \dots, k\}$ for L_p metric, we can optimize the inner problem in Eq 14 to get a set of activation scale factors $S = \{s_{p_i}^* \mid i = 1, 2, \dots, k\}$ by minimizing the given L_p metric. Because there are only a small number activation scale factors in a block, the p selection process executes quickly. The second step is to optimize to the quantization parameters for both activation and weight to minimize the local reconstruction loss using the selected p value. The output of the quantized block is used as the input of the next layer.

5. Experimental Results

To evaluate the effectiveness of our proposed DetPTQ, we experiment on the COCO [23] benchmark for 2D object detection and KITTI [9] benchmark for 3D object detection. We compare DetPTQ with the existing PTQ approaches on various CNN detectors, including RetinaNet [22], FasterRCNN [29] and PointPillar [18]. Performance of 2D detection is evaluated by standard COCO metrics with mean average precision (mAP) on the validation set. As to KITTI, we pick the standard metrics and report the 3D box and 2D bounding box results at AP40.

We set $P = \{1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5\}$ in our experiments.

5.1. Implementation Details

All the FP models in our paper use open-source codes from MMDetection [3] and MMDetection3D [7]. For COCO, we randomly pick a total of 256 training samples with a shorter edge to 800/600 pixels for ResNet [12] / MobileNetV2 [30] as the calibration dataset. As to KITTI, the number of calibration samples is set to 128. Following the implementation previous work [20, 32], the head of the network keeps full-precision, the first and the last layer are quantized to 8 bits. We execute block reconstruction for backbone and layer reconstruction for neck, respectively. We execute all experiments on Nvidia Tesla V100 GPU.

The balancing hyper-parameter α in Equation 10 is 0.1/0.001 for L_1 /IOU in the exploration of ODOL. To obtain the FP **positive boxes** in ODOL, the score threshold θ is 0.05 and the NMS threshold is 0.5. Given a p value for L_p , we optimize all activation scale factors in a block by Adam optimizer with the learning rate $3e-4$, iterations 5000 in Algorithm 1 line 6. We also optimize the scaling factors of convolution layers which do not belong to any block using Adam optimizer. The setting of local quantization reconstruction (i.e., Algorithm 1 line 14) is kept the same with QDrop, except that the warmup of rounding loss is 0.4.

5.2. Comparison with other PTQ Methods

As described in Section 3, PTQ can be divided into simple PTQ and advanced PTQ by whether optimizing the rounding variable. Our method can be applied to both simple and advanced PTQ. We try our ODOL-based adaptive L_p metric on the simple PTQ method and denote it as DetPTQ*, while we adopt DetPTQ in advanced PTQ to get higher quantization accuracy.

5.2.1 Result on COCO Benchmark

For simple PTQ, we compare the standard methods that grid searches the quantization parameters by minimizing

Table 4: Comparison on PointPillar with various PTQ algorithms on KITTI.

the MSE [26] and Cosine distance [33] between activations before and after quantization. We also compare a related work [27], which uses the variance information from BN [15] to define a BN-based L_p metric to conduct the local block-wise optimization. We denote this method as BN-based adaptive L_p .

According to the findings presented in Table 2, it is evident that the implementation of DetPTQ* can lead to a substantial enhancement in the simple PTQ method. It should be noted that relying solely on local information may not always yield accurate results. For instance, MSE, Cosine and BN-based adaptive L_p obtain 27.75, 21.59 and 24.77 mAP on W4A4 Faster RCNN-ResNet18, while DetPTQ* exhibits an improvement of 30.04 mAP for the simple PTQ method. Our DetPTQ* demonstrates remarkable improvement in the performance across all networks and bitwidth settings. This outcome highlights the efficacy of utilizing global information from the performance loss to derive a better quantization performance.

We also compare our method with strong advanced base-

lines including AdaRound, BRECQ and QDROP. The results are shown in Table 3. With W4A4 quantization, we observe that DetPTQ achieves less than 1% mAP drop on the ResNet-based object detection networks. As for W3A3 quantization, the task becomes harder but our method can also achieve significant improvement. In the most difficult W2A4 setting, our method can still improve the performance of the model in most cases. For instance, DetPTQ achieves 1.42% mAP improvement on RetinaNet-ResNet50 compared to the baseline QDrop. Taking all experiments together, our method is orthogonal to the selection of simple and advanced PTQ as well as provides a convincing uplift on the object detection network.

As certain models are unavailable, we present the results of other quantization methods utilizing their open-source codes with all FP models from MMDetection. It is possible that our values may differ from those reported in their papers.

Model	Variable	Optimal p	#Params
Layer1.1.Conv2	s_a	3.5	2
	$s_a + V$	3.5	2+1152
Layer4.1.Conv2	s_a	1.5	2
	$s_a + V$	1.5	2+9216

Table 5: Ablation study for different quantization parameters. We only quantize one layer (Layer1.1.Conv2 or Layer4.1.Conv2) on RetinaNet-ResNet18 at W3A3. #Params refers to the number of parameters to optimize.

5.2.2 Result on KITTI Benchmark

We choose PointPillar with SECOND backbone to evaluate the performance of DetPTQ on the KITTI benchmark for 3D object detection. For PointPillar, there is an additional head known as the direction prediction head. In addition to the localization offset, we decode the direction output to calculate the real coordinate, and then execute the localization loss (\mathcal{L}_{loc}) to measure the coordinate distance of **positive boxes** between the FP and quantized outputs.

As Table 4 shows, the results of our DetPTQ are indeed close to FP model with negligible accuracy drop on PointPillar-SECOND detector. At W4A8, we achieve a decrease of less than 1% compared to FP accuracy for the first time. As for the challenging W4A4, our DetPTQ achieves 0.61% \sim 3.61% improvement compared with strong baselines. For 3D box @AP40, we outperform QDrop by a large margin of 3.61%/3.22%/3.11% for easy/moderate/hard.

5.3. Ablation Study

5.3.1 The Quantization Parameters in ODOL

We only set the activation scale factor (s_a) as quantization parameters to optimize Eq 14 when given different p values, then select the lowest \mathcal{L}_{ODOL} and its corresponding p value. However, for advanced PTQ, there is another kind of weight parameter named the rounding variable (V), which determines whether the weight values round up or down. As shown in Table 5, we experiment with optimizing s_a and V jointly as quantization parameters and find the optimal p value of L_p metric. The experiments show that V is not sensitive to the optimization of optimal p value. Introducing V to the optimization will greatly increase the optimizing time, so we do not consider V . As to the weight scale factors, we follow the implementation of Qdrop and BRECQ with the optimization by minimizing MSE distance.

5.3.2 Effect of ODOL on Different Functions

To show the effectiveness of different functions for the Object Detection Output Loss, we quantize RetinaNet-ResnetNet18 and Faster RCNN-ResNet18 at W4A4 as ex-

Model	Metric				mAP
	L_2	KL	L_1	IOU	
RetinaNet-ResNet18	✓		✓		31.07
	✓	✓	✓		31.12
				✓	30.21
Faster RCNN-ResNet18		✓		✓	30.64
	✓		✓		33.41
	✓	✓	✓		33.82
			✓	33.04	
		✓		✓	33.11

Table 6: Ablation study of different combination for ODOL. We mark a ✓ when adopt the loss function.

amples to conduct the ablation study. Table 6 shows the experimental results. KL and L_2 measure the distance between the quantized and FP feature map for the classification head. IOU loss measures the spatial difference of bounding boxes from quantized and FP output. L_1 is leveraged for the difference of coordinate distance. We observe that choosing KL+ L_1 as ODOL yields the best quantization result among all metrics. Hence we finally set KL+ L_1 as the ODOL functions to represent the task information of object detection to guide the optimization of the adaptive L_p metric.

KL divergence is widely used to measure the error of probability distribution. So it can better reflect the error of classification features than MSE. We also postulate that minimizing the difference of coordinate distance (L_1) directly rather than spatial difference (IOU loss) can better represent localization error for PTQ.

5.3.3 Comparison with other Metrics

To illustrate the superiority of our ODOL-based L_p metric for a broader comparison, we conduct further experiments to compare it with other metrics. In Table 7, we compare the adaptive BN-based L_p and local MSE with our ODOL-based L_p on the advanced PTQ method. Minimizing the distance of intermediate feature maps before and after quantization, those two metrics are denoted as the local metric. Our DetPTQ introduces the global performance loss information to determine the L_p metric. We can see that the ODOL-based adaptive L_p metric can improve the accuracy by 0.58% compared with the MSE at the W4A4 bit setting. The ODOL also outperforms the BN to guide the p value and improve by 2.36% on RetinaNet-ResNet18 compared with based on BN at W4A4.

6. Conclusion

In this paper, we explored the application of post-training quantization on object detection networks. At first, we observed that the parameter p in L_p metric has a significant in-

Method	Metric	Bits(W/A)	
		W4A4	W3A3
Local	MSE	30.54	28.48
Local	BN-based adaptive L_p	28.76	27.16
Global	ODOL-based adaptive L_p	31.12	29.30

Table 7: Results of the parameter optimization by different metrics on RetinaNet-ResNet18 at W4A4.

fluence on quantization for object detection networks. And we indicated that it is necessary to set an adaptive L_p metric. To solve these problems, we propose the Object Detection Output Loss (ODOL) as an approximation of performance loss and then optimize the p value using ODOL as the reconstruction quantization loss. We proposed the framework, DetPTQ, which achieved the SOTA on networks for both 2D and 3D object detection tasks.
