Actively Learning Reinforcement Learning: A Stochastic Optimal Control Approach

Mohammad S. Ramadan¹, Mahmoud A. Hayajnh², Michael T. Tolley³, Kyriakos G. Vamvoudakis²

Abstract—In this paper we propose a framework towards achieving two intertwined objectives: (i) equipping reinforcement learning with active exploration and deliberate information gathering, such that it regulates state and parameter uncertainties resulting from modeling mismatches and noisy sensory; and (ii) overcoming the huge computational cost of stochastic optimal control. We approach both objectives by using reinforcement learning to attain the stochastic optimal control law. On one hand, we avoid the curse of dimensionality prohibiting the direct solution of the stochastic dynamic programming equation. On the other hand, the resulting stochastic control inspired reinforcement learning agent admits the behavior of a dual control, namely, caution and probing, that is, regulating the state estimate together with its estimation quality. Unlike exploration and exploitation, caution and probing are employed automatically by the controller in real-time, even after the learning process is concluded. We use the proposed approach on a numerical example of a model that belongs to an emerging class in system identification. We show how, for the dimensionality of the stochastic version of this model, Dynamic Programming is prohibitive, Model Predictive Control requires an expensive nonlinear optimization, and a Linear **Ouadratic Regulator with the certainty equivalence assumption** leads to poor performance and filter divergence, all contrasting our approach which is shown to be both: computationally convenient, stabilizing and of an acceptable performance.

I. INTRODUCTION

The significance and proliferation of Reinforcement Learning (RL) across various disciplines are by now selfevident [20]. RL is an umbrella of algorithms that are rooted in the concept of stochastic approximation [5], [20], [14]. At its core, it tries to solve an optimal control problem through maximizing some notion of a cumulative reward. Yet, with this promise of RL algorithms, a tough challenge arises when applying learned policies to real-world applications [8]. These policies, trained in lab simulations or controlled environments, may suffer a degradation in performance or exhibit an unsafe behavior [14]. This stems from modeling mismatches and discrepancies between the training environment and real-world conditions.

The field of stochastic optimal control (SOC) [6, ch. 25], also known as dual control [21], yields two key behaviors:

Fig. 1. A graphical overview of stochastic optimal control: the controller is not only concerned with regulating the state estimate (mean, mode, ... etc), but also regulating the state uncertainty (or the state estimate quality) via driving the system through high observable regions, for instance, regions of better signal-to-noise ratio (SNR) and/or of more/better sensors. The green and pink regions correspond to state uncertainty propagation along two different trajectories. The trajectory in pink, resembling a trajectory under stochastic optimal control, takes into consideration regulating uncertainty, and hence, in its path to the origin, it chooses the path of higher observability.

caution and probing [11]. Caution refers to the control actions that prevent undesirable outcomes when the system is under uncertainty, while probing involves actions aimed at gathering information about the system's uncertain parameters and states. These concepts play a central role in ensuring safety while enhancing the system's learning capabilities and state observability. In general, SOC is computationally prohibitive, except for the simplest cases. Relying on dynamic programming to solve such high dimensional problems is hopeless [3], due to the curse of dimensionality.

The potential of both RL and SOC is limited by their inherent challenges. Here, we utilize each to address the limitation of the other. Specifically, the modeling mismatch problems inherent to RL can be alleviated by the caution and probing effects of SOC. Caution imposes restrictions on the RL agent behavior under uncertainty and modelling mismatch, acting as a safeguard against false perception. Probing, moreover, aims to correct the modelling uncertainty and to create an accurate perception of the environment. On the other hand, RL, possibly together with a neural net [12] as a function approximator, can mitigate the computational burden of SOC. These hypothesized mutual benefits serve as the motivation for the work we present here.

Early work in the RL community acknowledged the need for stochastic policies when the agent has limited or distorted access to the states [9]. The randomness intro-

duced by stochastic policies diversifies chosen actions and hence achieves "artificial probing" in a sense analogous to persistence of excitation in control theory and system identification [13]. While this method diversifies actions to enhance learning, it may also compromise system safety and stability. In this paper, we propose a learning architecture that addresses RL's vulnerability to modeling uncertainties and aims to alleviate the computational burdens of SOC. Therefore, we seek a controller which, unlike those with stochastic policies, seeks deliberate probing when information gathering is required, and does so cautiously: respecting safety and performance conditions.

II. PROBLEM FORMULATION

Consider a class of discrete-time nonlinear systems described $\forall k \in \mathbb{N}$ by,

$$x_{k+1} = f(x_k, u_k) + w_k,$$
 (1a)

$$y_k = g(x_k) + v_k, \tag{1b}$$

where $x_k \in \mathbb{R}^{r_x}$ is the state vector, $u_k \in \mathbb{R}^{r_u}$ is the control input, $y_k \in \mathbb{R}^{r_y}$ is the output signal, and $w_k \in \mathbb{R}^{r_x}$, $v_k \in \mathbb{R}^{r_y}$ are exogenous disturbances. The functions f and g are known and differentiable in x_k , and f is thrice differentiable in u_k . The stochastic processes, $\{v_k\}$ and $\{w_k\}$, are assumed independent and identically distributed with continuous densities of zero means and positive definite symmetric covariances $\Sigma_w \succ 0$ and $\Sigma_v \succ 0$, respectively. These sequences are independent from each other and from x_0 , the initial state, which has a continuous density $\pi_{0|0}$ of mean $x_{0|0}$ and covariance $\Sigma_{0|0} \succ 0$. The functions f and g are continuously differentiable with respect to their arguments.

The goal is to construct a causal control law, i.e., a control law that is only dependent upon the data accessible up until the moment of evaluating the control action, or, $u_k = u_k(\mathcal{Z}_k)$, where $\mathcal{Z}_k = \{y_0, \ldots, y_k, u_0, \ldots, u_{k-1}, \pi_{0|0}\}$. This law has to minimize the cost functional

$$J_N = \mathbb{E}\left\{\gamma^N x_N^\top Q x_N \sum_{k=0}^{N-1} \gamma^k \left[x_k^\top Q x_k + u_k^\top R u_k\right]\right\}, \quad (2)$$

where the discount factor $\gamma \in (0, 1)$, the inputs $u_k \in \mathbb{U}$, where U is a bounded set, and the symmetric matrices $Q \succeq 0, R \succ 0$. The expectation and constraint satisfaction probabilities are taken with respect to all the random variables, i.e., x_0, w_k , and v_k , for all k.

Assumption 1. (Bounded input bounded state condition): The disturbance $w_k \subset \mathbb{W} \subset \mathbb{R}^{r_x}$ and the control input $u_k \in \mathbb{U} \subset \mathbb{R}^{r_u}$ belonging to the bounded sets \mathbb{W} , \mathbb{U} , result in an invariant compact set \mathbb{X} , i.e., $x_0 \in \mathbb{X} \implies x_k \in \mathbb{X}$, $\forall k \ge 0$.

In general nonlinear systems, as in (1a), it is immaterial to separate states from unknown or time-varying parameters. Using the concept of the state augmentation [10, p. 281] the parameters of a system can be augmented in the state vector, which, in contrast to linear systems, augmentation for nonlinear systems does not fundamentally alter the structure of the system; it is nonlinear both ways. Therefore, we make no distinction between states and parameters in the following sections, hence, regulating state uncertainty encompasses parameter learning and modelling mismatch reduction [4].

III. BACKGROUND: STOCHASTIC OPTIMAL CONTROL

The vector x_k in (1a) retains its Markovian property due to the whiteness of $\{w_k\}_k$. Moreover, the observation y_k is conditionally independent when conditioned on x_k ; $\{v_k\}_k$ in (1) is also white. These assumptions are typical in partially observable Markov decision processes [5]. Under these conditions, the state x_k cannot be directly accessed; it can only be inferred through the observation y_k , which typically is not equal to x_k . The vector x_k is only a state in the Markovian sense, that is

$$p(x_{k+1} \mid x_k, x_{k-1}, \dots, x_0, u_k, \dots, u_0) = p(x_{k+1} \mid x_k, u_k).$$

For a decision maker or a control designer (or the learner as in [9]), an alternative "state" is required. That is, from a practical standpoint, the minimal accessible piece of information adequate to reason about the system's future safety and performance. Consequently, this discussion gives rise to the concept of the *information state*, which, at time-k, is the state filtered density function $\pi_{k|k} = p(x_k \mid Z_k)$ [11]. As an "informative statistic," a term used by [19], it roughly means a statistic that is sufficiently informative to enable a desired control objective. However, the information state is infinite dimensional in general, which renders its applicability infeasible, computationally. In the next subsections, we shall explain the sources of this infeasibility and provide a framework to alleviate them.

A. Separation

Adopting the information state $\pi_{k|k}$, a causal controller has the form $u_k = u_k(\pi_{k|k})$. This formulation of the control law allows the interpretation of SOC as comprising two distinct steps [7, ch. 25]:

- 1) Tracking $\pi_{k|k}$, that is, a Bayesian filter that propagates the information state [11].
- 2) A law that assigns a value u_k to each information state provided by the filter, such that this law minimizes (2).

In the linear Gaussian state-space model case, the information state takes an equivalent finite dimensional characterization: the state conditional mean and covariance. If the system is unconstrained, the optimal control is indifferent to the state covariance and is only a function of the mean. This explains the separation principle in LQG control design [2, ch. 8]. This separation principle differs from that in the realm of SOC. The latter strictly denotes the two-step interpretation listed above.

As pointed out by [21], tracking the information state $\pi_{k|k}$ does not solve the problem; a convenient approximation to the Bayesian filter is typically less cumbersome than finding the SOC. The next subsection is a brief introduction to the Bayesian filter, which is then used to construct the dynamic programming equation for the stochastic case. 1) The Bayesian Filter: The equivalent stochastic representation of system (1), $\forall k \in \mathbb{N}$: the transition kernel $x_{k+1} \sim p(x_{k+1} \mid x_k, u_k)$ and the measurement likelihood $y_k \sim p(y_k \mid x_k)$, can be achieved, similar to [17], due to the whiteness of w_k and v_k .

The information state can be propagated, at least in principle, through the Bayesian filter, which consists of the following two steps: the time update

$$p(x_{k+1} \mid u_k, \mathcal{Z}_k) = \int p(x_{k+1} \mid u_k, x_k) p(x_k \mid \mathcal{Z}_k) \, \mathrm{d}x_k, \quad (3)$$

and the measurement Update

$$p(x_{k+1} \mid \mathcal{Z}_{k+1}) = \frac{p(y_{k+1} \mid x_{k+1})p(x_{k+1} \mid u_k, \mathcal{Z}_k)}{\int p(y_{k+1} \mid x_{k+1})p(x_{k+1} \mid u_k, \mathcal{Z}_k) \, \mathrm{d}x_{k+1}}.$$
 (4)

Notice that to move from the filtered density at time-k to k + 1, the values of u_k and y_{k+1} are used. To simplify the notation, we denote $\pi_{k|k} = p(x_k \mid Z_k)$ and $\pi_{k+1|k} = p(x_{k+1} \mid u_k, Z_k)$, and define the mapping

$$\pi_{k+1|k+1} = T(\pi_{k|k}, u_k, y_{k+1}), \tag{5}$$

where T maps $\pi_{k|k}$ to $\pi_{k+1|k}$ using u_k in (3), then to $\pi_{k+1|k+1}$ using y_{k+1} in (4).

2) Stochastic Dynamic Programming: A causal control law uses only the available information up to the moment of evaluating this law. In accordance with the principle of optimality, when making the final control decision, denoted as u_{N-1} , and given the available information then \mathcal{Z}_{N-1} , the optimal cost can be determined as follows

$$\min_{u_{N-1}\in\mathbb{U}}\mathbb{E}\left\{x_{N-1}^{\top}Qx_{N-1}+u_{N-1}^{\top}Ru_{N-1}+\gamma x_{N}^{\top}Qx_{N}\mid u_{N-1},\mathcal{Z}_{N-1}\right\},$$

where the expectation is with respect to x_{N-1} and w_{N-1} . Notice that above expression, when x_{N-1} is random, is solely a function of the information state $\pi_{N-1|N-1}$; the disturbance w_{N-1} is marginalized over through the expectation, and u_{N-1} is the decision variable of the minimization. That is,

$$V_{N-1}(\pi_{N-1|N-1}) = \min_{u_{N-1} \in \mathbb{U}} \mathbb{E} \left\{ x_{N-1}^{\top} Q x_{N-1} + u_{N-1}^{\top} R u_{N-1} + \gamma x_{N}^{\top} Q x_{N} \mid u_{N-1}, \mathcal{Z}_{N-1} \right\}.$$
(6)

Define $V_N(\pi_{N|N}) = \mathbb{E} \{ x_N^\top Q x_N \mid Z_N \}$. The following are needed to derive the stochastic Dynamic Programming equation.

Lemma 1. (Smoothing theorem [16, ch. 10]): Let $(\Omega, \mathcal{A}, \mathbf{P})$ be a probability space, and $\chi : \Omega \to \mathbb{R}$ a measurable and L^1 function, i.e., $\mathbf{E}|\chi| < \infty$, where \mathbf{E} is the expectation (over \mathbf{P}). Let the σ -algebras $\mathcal{A}_0 \subset \mathcal{A}_1 \subset \mathcal{A}$, then

$$\mathbf{E}\left\{\chi \mid \mathcal{A}_{1}\right\} = \mathbf{E}\left\{\mathbf{E}\left\{\chi \mid \mathcal{A}_{0}\right\} \mid \mathcal{A}_{1}\right\}. \quad \Box$$

Corollary. The expression $\mathbb{E} \{ x_N^\top Q x_N \mid u_{N-1}, \mathcal{Z}_{N-1} \}$, which is finite, by Assumption 1, can be re-written as

$$\mathbb{E} \left\{ x_N^\top Q x_N \mid u_{N-1}, \mathcal{Z}_{n-1} \right\} = \mathbb{E} \left\{ \mathbb{E} \left\{ x_N^\top Q x_N \mid \mathcal{Z}_N \right\} \mid u_{N-1}, \mathcal{Z}_{n-1} \right\}, \\= \mathbb{E} \left\{ V_N(\pi_{N|N}) \mid u_{N-1}, \mathcal{Z}_{n-1} \right\}. \quad \Box$$

Using the above result and (5) in (6), we have

$$V_{N-1}(\pi_{N-1|N-1}) = \\ \min_{u_{N-1} \in \mathbb{U}} \mathbb{E} \left\{ x_{N-1}^{\top} Q x_{N-1} + u_{N-1}^{\top} R u_{N-1} + \gamma V_N(T(\pi_{N-1|N-1}, u_{N-1}, y_N) \mid u_{N-1}, \mathcal{Z}_{N-1} \right\}.$$
(7)

This is the first backward iteration of the *stochastic dy*namic programming equation, through which, a minimizing u_{N-1} is assigned to each information state $\pi_{N-1|N-1}$. This step is repeated for all time-steps $N-2, \ldots, 0$.

Solving the stochastic dynamic programming equation is computationally prohibitive, in general, primarily because of the infinite dimensionality of the information state. In the next section, we approximate the Bayesian filter by the EKF, reducing the information state into a finite-dimensional object.

IV. METHODOLOGY

In this section we outline the EKF algorithm, and its "wide sense" (mean and covariance) approximation of the information state. We then adapt the cost in (2) to the new approximate wide-sense information state. A few, mainly cosmetic, changes to this adapted cost are implemented to make it align with the assumptions/notation of the RL algorithm which will be outlined subsequently.

A. EKF

We replace the infinite dimensional information state $\pi_{k|k}$ by a finite dimensional approximate one, namely, the state conditional mean vector $\hat{x}_{k|k}$ and covariance matrix $\Sigma_{k|k}$.

Let

$$\hat{x}_{k|k} = \mathbb{E} \{ x_k \mid \mathcal{Z}_k \}, \quad \hat{x}_{k|k-1} = \mathbb{E} \{ x_k \mid u_{k-1}, \mathcal{Z}_{k-1} \}, \\ \Sigma_{k|k} = \mathbb{E} \{ (x_k - \hat{x}_{k|k}) (x_k - \hat{x}_{k|k})^\top \mid \mathcal{Z}_k \}, \\ \Sigma_{k|k-1} = \mathbb{E} \{ (x_k - \hat{x}_{k|k-1}) (x_k - \hat{x}_{k|k-1})^\top \mid u_{k-1}, \mathcal{Z}_{k-1} \}$$

The EKF, similarly to the Bayesian filter, consists of the following two major steps:

• Measurement-update

$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + L_k \left(y_k - g(\hat{x}_{k|k-1}) \right), \\ \Sigma_{k|k} = \Sigma_{k|k-1} - L_k H_k \Sigma_{k|k-1}.$$

• Time-update

$$\hat{x}_{k+1|k} = f(\hat{x}_{k|k}, u_k), \quad \Sigma_{k+1|k} = F_k \Sigma_{k|k} F_k^\top + \Sigma_w,$$

which can be combined to write,

$$\hat{x}_{k+1|k+1} = f(\hat{x}_{k|k}, u_k) + L_{k+1} \left(y_{k+1} - g(\hat{x}_{k+1|k}) \right), \quad (8)$$

$$\Sigma_{k+1|k+1} = \left(I - L_{k+1} H_{k+1} \right) \left(F_k \Sigma_{k|k} F_k^\top + \Sigma_w \right), \quad (9)$$

where

$$L_{k} = \Sigma_{k|k-1} H_{k}^{\top} \left(H_{k} \Sigma_{k|k-1} H_{k}^{\top} + \Sigma_{v} \right)^{-1},$$

$$F_{k} = \left. \frac{\partial f(x, u_{k})}{\partial x} \right|_{x = \hat{x}_{k|k}}, \quad H_{k} = \left. \frac{\partial g(x)}{\partial x} \right|_{x = \hat{x}_{k|k-1}},$$

and $\hat{x}_{0|0}$, $\Sigma_{0|0}$ are the initial state x_0 mean and covariance.

In general, the above conditional means and covariances are not exact; the state conditional densities $\pi_{k|k}$ are non-Gaussian due to the nonlinearities. Hence, $\hat{x}_{k|k}$ and $\sum_{k|k}$ are merely approximations to the conditional mean and covariance of x_k [1]. Define

$$\hat{\pi}_{k+1} = \hat{T}(\hat{\pi}_k, u_k, y_{k+1}),$$
(10)

where the tuple $\hat{\pi}_k = (\hat{x}_{k|k}, \Sigma_{k|k})$. Here \hat{T} is a surrogate approximate mapping to T in (5). The mapping \hat{T} applies the steps (8) of the EKF to $\hat{x}_{k|k}, \Sigma_{k|k}$, using u_k and y_{k+1} , and generates $\hat{x}_{k+1|k+1}$ and $\Sigma_{k+1|k+1}$.

B. Cost

The first two moments provided by the EKF are sufficient to evaluate the expectation of the finite-horizon cost function in (2), due to the quadratic stage costs.

We apply Lemma 1 to the cost (2), conditioning on the information available at the time-step of each additive term. That is, we write each additive term as $\mathbb{E} \{ \mathbb{E} \{ x_k^\top Q x_k + u_k^\top R u_k \mid \mathcal{Z}_k \} \}$. If we then write $x_k = \hat{x}_{k|k} + \tilde{x}_k$, where $\mathbb{E} \{ \tilde{x}_k \mid \mathcal{Z}_k \} = 0$, each additive term takes the form

$$\mathbb{E}\left\{\mathbb{E}\left\{\left(\hat{x}_{k|k}+\tilde{x}_{k}\right)^{\top}Q(\hat{x}_{k|k}+\tilde{x}_{k})+u_{k}^{\top}Ru_{k}\mid\mathcal{Z}_{k}\right\}\right\},\\=\mathbb{E}\left\{\hat{x}_{k|k}^{\top}Q\hat{x}_{k|k}+tr(Q\Sigma_{k|k})+u_{k}^{\top}Ru_{k}\right\},$$

after ignoring the zero mean cross-terms, and use the linearity of \mathbb{E} and the circularity of the *tr* (trace) operator. Therefore we can re-write the cost (2)

$$J_{N} = \mathbb{E}\left\{\gamma^{N}\left[\hat{x}_{N|N}^{\top}Qx_{N|N} + tr(Q\Sigma_{N|N})\right] + \sum_{k=0}^{N-1}\gamma^{k}\left[\hat{x}_{k|k}^{\top}Q_{k}\hat{x}_{k|k} + tr(Q\Sigma_{k|k}) + u_{k}^{\top}Ru_{k}\right]\right\}, \quad (11)$$

and the stochastic Dynamic Programming equation (7) as

$$V_{N-1}(\pi_{N-1|N-1}) = \min_{u_{N-1} \in \mathbb{U}} \left\{ \hat{x}_{N-1|N-1}^{\top} Q \hat{x}_{N-1|N-1} + tr(Q \Sigma_{N-1|N-1}) + u_{N-1}^{\top} R u_{N-1} + \gamma \mathbb{E} \left\{ V_N(T(\pi_{N-1|N-1}, u_{N-1}, y_N) \mid u_{N-1}, \mathcal{Z}_{N-1}) \right\} \right\}.$$
(12)

The following is a known result in SOC, which we present to show that minimizing (11) reduces to the LQG control in the linear case.

Corollary. (*The separation principle [2]*): If the system (1) is linear, the minimizing control law is $u_k = K_k \hat{x}_{k|k}$, where K_k is the time-varying LQR gain of the deterministic (state fully observed and noise is zero) version of the problem and $\hat{x}_{k|k}$ is the conditional mean of the Kalman filter.

Proof. This is true since in the linear case $\Sigma_{k|k}$ evolves independently of u_0, \ldots, u_k , hence, can be omitted from (11) when minimizing for the control law, resulting in the canonical deterministic LQR problem. Equivalently, it can be shown that V_{N-1} is only a function of $\hat{x}_{N-1|N-1}$, and constant over $\Sigma_{N-1|N-1}$.

In the nonlinear case however, $\sum_{k|k}$'s evolution depends on the jacobians F_k , H_k , which in turn depend on u_k and $\hat{x}_{k|k}$. Therefore, a SOC takes into consideration regulating the state uncertainty $\sum_{k|k}$ to achieve system and filter stability, and minimize the cost (11).

C. Deterministic Policy Gradient

Among the numerous algorithms within the scope of RL, we opt for the Deterministic Policy Gradient (DDPG) algorithm [18], in particular, its deep neural net implementation [12]. While we find this algorithm convenient within the context of this paper—primarily due to its ability to handle continuous action spaces—our choice does not impose strong preferences on the selection of other RL algorithms.

We first show that according to our assumptions and formulation, the stage-costs in the cost function (11) are bounded (by Assumption 1 and assuming uniform observability [15]), and hence the cost is bounded as $N \to \infty$ (sandwiched by a geometric series), i.e. $\lim_{N\to\infty} J_N \to J_{\infty} < \infty$. Furthermore, its minimum corresponds to the fixed point solution of (12), i.e., when $V_{N-1} = V_N = V_{\infty}$ [5, ch. 7].

Having a well-defined cost and value functions over $N \rightarrow \infty$ is important as a huge portion of RL algorithms considers the infinite-horizon case. Another straightforward adaptation required is that the common notation in RL is to maximize the value, compared to minimizing the cost in optimal control. By simply defining the reward signal as the negative of the stage-cost in (11),

$$r(\hat{\pi}_k, u_k) = -\mathbb{E}\left\{\hat{x}_{k|k}^\top Q_k \hat{x}_{k|k} + tr(Q\Sigma_{k|k}) + u_k^\top R_k u_k\right\},\,$$

which, as discussed above, is bounded for all k.

Analogous to (12), the state-action value function Q_0 [5],

$$Q_0(\hat{\pi}_k, u_k) = r(\hat{\pi}_k, u_k) + \gamma \mathbb{E} \left(Q_0(\hat{T}(\hat{\pi}_k, u_k, y_{k+1})) \right),$$

which its existence is immediate from the existence of V_{∞} . We use a neural network control policy $u_k = \mu_{\theta}(\hat{\pi}_k)$, where θ denotes its weights and biases. Writing the reward representation of the cost (11) (its negative),

$$J_{\theta}(\hat{\pi}_0) = \mathbb{E}\left\{\sum_{k=0}^{\infty} \gamma^k r(\hat{\pi}_k, \mu_{\theta}(\hat{\pi}_k))\right\} = -J_{\infty}.$$

The policy gradient theorems seek to find a description of the gradient $\nabla_{\theta} J_{\theta}$ which is convenient for computation. We now present the Deterministic Policy Gradient Theorem of [18], adapted for the case of SOC.

Theorem. (Deterministic Policy Gradient for SOC): Under the formulation in Section II, Assumption 1, filter stability and uniform observability (boundedness of (8)), the following identity holds true:

$$\nabla_{\theta} J_{\theta} = \mathbb{E} \left| \nabla_{u} Q_{0}(\hat{\pi}, u) \nabla_{\theta} \mu_{\theta}(\hat{\pi}) \right|.$$

Proof. By the formulation in Section II and the hypothesis above: (i) the transition density $p(\hat{\pi}_{k+1} \mid \hat{\pi}_k, u_k)$, induced by the dynamics (10), is twice differentiable in u_k , and continuous in π_{k+1} and π_k , (ii) the policy, being a neural net, is twice differentiable with respect to its parameters (for most activation functions), (iii) the reward function r, being quadratic, is differentiable in all of its arguments, (iv) the reward and the transition densities, being continuous, themselves and their jacobians in u_k , in $\hat{\pi}_k$ and u_k over the compact set $\mathbb{X} \times \mathbb{U}$, are bounded. The points (i)-(iv) imply the regularity assumptions in [18, Appendix A], and hence the result.

In DDPG [12], Q_0 is also approximated by a neural net Q_{ψ} with parameters ψ updated via temporal difference methods. While the above gradient is used to update the control policy neural net μ_{θ} . Algorithm 1 is the DDPG algorithm adapted for the information state (instead of the state). It does not include the target networks as in [12], which can be augmented to Algorithm 1 to improve learning stability.

Algorithm 1 Actively Learning RL via DDPG

Randomly initialize the weights θ , ψ of the neural nets Q_{ψ} and μ_{θ} ; Initialize replay buffer \mathcal{R} ; for episode $= 1, 2, \dots$ do Randomly sample an initial information state $\hat{\pi}_0$ = $\{\hat{x}_0, \Sigma_0\}$ and a true state x_0 ; for k = 0, ..., N - 1 do Sample control actions $u_k = \mu_{\theta}(\hat{\pi}_k) + \eta$ where η is an exploration noise; Apply u_k in (1a) to sample the true x_{k+1} ; Using x_{k+1} in (1b), sample the true y_{k+1} ; Using $\hat{\pi}_k$, u_k and y_{k+1} , evaluate $\hat{\pi}_{k+1}$ using (10); Calculate the reward $r(\hat{\pi}_k, u_k)$; Store the tuple $(\hat{\pi}_k, u_k, r(\hat{\pi}_k, u_k), \hat{\pi}_{k+1})$ in \mathcal{R} ; Sample a minibatch $\{(\hat{\pi}_i, u_i, r(\hat{\pi}_i, u_i), \hat{\pi}_{i+1}), i =$ $1,\ldots,M$ of \mathcal{R} ; Set $z_i = r(\hat{\pi}_i, u_i) + \gamma Q_{\psi}(\hat{\pi}_{i+1}, \mu_{\theta}(\hat{\pi}_{i+1}));$ Update the critic network Q_{ψ} by minimizing the loss $\frac{1}{M} \sum_{i=1}^{M} (z_i - Q_{\psi}(\hat{\pi}_i, u_i))^2$, w.r.t. ψ ; Update the policy network μ_{θ} using the sample

Update the policy network μ_{θ} using the sample average policy gradient

$$\nabla_{\theta} J_{\theta} \approx \frac{1}{M} \sum_{i=0}^{M} \nabla_{u} Q_{\psi}(\hat{\pi}_{i}, u) \mid_{u=\mu_{\theta}(\hat{\pi}_{i})} \nabla_{\theta} \mu_{\theta}(\hat{\pi}_{i});$$

triangle only in Algorithm 1.

V. NUMERICAL EXAMPLE

In this section we implement Algorithm 1 on a system with varying state observability over the state-space \mathbb{R}^3 . This simple example, although 3-dimensional, but 9-dimensional in the information state in (10) (3 for the states and 6 for the lower (or upper) triangle of the state covariance matrix), therefore, prohibitive for Dynamic Programming, and results in a complicated nonlinear programming for Model Predictive Control. Instead, we demonstrate here how Algorithm 1 can be used to obtain a stochastic control. We compare the resulting closed-loop behavior to that obtained via LQG (LQG denotes an LQR with an EKF (in this example)).

Consider the model

$$x_{k+1} = \begin{bmatrix} .92 & .2 & -.1 \\ 0 & .95 & -.3 \\ 0 & 0 & .93 \end{bmatrix} x_k + \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix} u_k + w_k,$$
$$y_k = \frac{1}{27} \text{ELU}((x_k(1))^3) + v_k,$$

where $x_k(1)$ is the first entry of x_k , w_k and v_k obey the assumptions listed under (1), and moreover, $w_k \sim \mathcal{N}(0, \Sigma_w)$ and $w_k \sim \mathcal{N}(0, \Sigma_v)^1$, where $\Sigma_v = 0.2$, $\Sigma_w = 0.5 \mathbb{I}_{3\times 3}$. The ELU function is the exponential linear unit, heavily used in deep learning. It behaves as x when x > 0 and $\text{ELU}(x) \approx$ -1 for x < 0.

The choice of this system is due to its proliferation in system identification literature, as it belongs to the emerging Hammerstein–Wiener models, or linear dynamics composed with algebraic nonlinearities [22]. More importantly, this function admits variable x_k to y_k sensitivity, which in turn affects the observability of the system. For $x_k(1) < 0$, this sensitivity vanishes, and x_k is no longer observables by the means of y_k . Therefore, it is the duty of a stochastic controller to take this into consideration: frequently seeking $x_k(1) > 0$ for better observability (information gathering). Such a model can be effective in modeling deteriorating sensors quality or signal-to-noise ratio in a certain region of the state-space.

We use $Q = \mathbb{I}_{3\times 3}$ and R = 1, and a discount factor $\gamma = 0.95$. The constraints are $u_k \in \mathbb{U} = [-5, 5]$, which we enforce by using a saturated parameterized policy.

Deterministic policy gradient methods [18] use the actorcritic learning architecture: the actor being the control policy, and the critic is its corresponding policy evaluation in the shape of an action-value function. In this example, both networks are feedforward, with one hidden layer of size 64. The actor network receives two inputs: the information state elements $\hat{x}_{k|k}$ and (the lower triangle of) $\sum_{k|k}$ }. The output of this network is the control u_k . The critic network, approximating the action value function, takes three input values: both of the information state elements as well as the corresponding control action u_k , and it outputs $Q_0(\hat{\pi}_k, u_k)$.

¹The notation $\mathcal{N}(\mu, \Sigma)$ denotes a Gaussian density with mean vector μ and covariance matrix Σ .

We use mini-batch learning, with batches of size 64 of tuples $(\hat{\pi}_{k|k}, u_k, r_k, \hat{T}(\hat{\pi}_k, u_k, y_{k+1}))$, and with learning rate 10^{-3} . Figure 2 shows the statistics of the normalized accumulative reward of 50 different training trials, all started from different randomized initial weights. The figure also shows the trial we picked to generate the subsequent closed-loop results. These 50 training trials altogether consumed about 75 minutes in computation, relying on an NVIDIA V-100 GPU².

Fig. 2. The average reward of a 50 different runs of Algorithm 1 is shown in dark blue, while the shaded area is the corresponding two standard deviations about the average. In orange is the run with the highest terminal reward, which its corresponding controller is used to generate the closed-loop results below.

Fig. 3. LQG (left) vs RL dual control (right): For each figure, the vertical axis is the magnitude of: the mean $\hat{x}_{k|k}(1)$ and $tr(\Sigma_{k|k})$ which are shown in dark blue and orange, respectively, and the true state $x_k(1)$ shown in green.

An LQG control is first applied: $u_k = K\hat{x}_{k|k}$, where $\hat{x}_{k|k}$ is provided by the EKF and K is the LQR gain of the deterministic version of the system. The result of this LQG control is shown to the left of Figure 3, which displays the true state deviation and *filter divergence* [1], [10]. This divergence is caused mainly by the LQG controller "insisting" on driving the state to the origin, making the system vulnerable to loss of observability if the true state $x_k(1)$ escapes to its negative side. This issue has been handled by the RL control resulting from our approach. To the right of Figure 3, it can be seen that our controller does not prioritize only driving the state estimate to the origin, but also deliberately seeking some level of observability by continuously pushing $x_k(1)$ towards the positive side, whenever the uncertainty measure $tr(\Sigma_{k|k})$ starts rising.

VI. CONCLUSION

The presented framework is to produce an RL agent with attributes from SOC, namely, caution (safety) and probing (active learning). Our approach is built on the uniform observability and filter stability assumptions which are typically satisfied, due to the widespread use of the EKF, which signals its convenience. In generally, however, what qualifies as a "sufficient" approximation to the information state is a rather complicated question, and one might be required to adapt our derivations to a different Bayesian filter (e.g. a particle filter), if the EKF is not sufficient.

In addition to the uncertainty propagator, our future work is aimed at crafting the reward signal; to generate a different caution vs probing balance: for instance, prioritizing filter stability (or its accuracy) by including the true ($||x_k - \hat{x}_{k|k}||$) estimation error or by further penalizing the state covariance term in the reward signal.
