Abstract

Training of modern large neural networks (NN) requires a combination of parallelization strategies encompassing data, model, or optimizer sharding. When strategies increase in complexity, it becomes necessary for partitioning tools to be 1) expressive, allowing the composition of simpler strategies, and 2) predictable to estimate performance analytically. We present PartIR, our design for a NN partitioning system. PartIR is focused on an incremental approach to rewriting and is hardware-and-runtime agnostic. We present a simple but powerful API for composing sharding strategies and a simulator to validate them. The process is driven by high-level programmer-issued partitioning tactics, which can be both manual and automatic. Importantly, the tactics are specified separately from the model code, making them easy to change. We evaluate PartIR on several different models to demonstrate its predictability, expressibility, and performance.

1 Introduction

The recent growth of NN training requirements has significantly outpaced the increase in accelerator memory and FLOPS. Google TPU [\[26,](#page-13-0)[27\]](#page-13-1) v2 reports 46 TFLOPS / 16 GB of high-bandwidth memory (HBM) per chip, while v4 reports 275 TFLOPS / 32 GB [\[12\]](#page-12-0) over a period where model parameters - consequently FLOPS - requirements increased by 10^4 [\[8\]](#page-12-1). Due to the need to scale out, today's large NNs [\[5,](#page-12-2) [11,](#page-12-3) [20,](#page-13-2) [44,](#page-14-0) [58,](#page-15-0) [60\]](#page-16-0) are trained on many accelerators through a mixture of parallelism strategies.

User-driven partitioners [\[32,](#page-14-1) [53,](#page-15-1) [67\]](#page-16-1) make it possible to express a wide range of parallelism strategies in high-level ML frameworks [\[1,](#page-12-4) [4,](#page-12-5) [41\]](#page-14-2), without requiring ML engineers to explicitly write distributed systems code using low-level communication primitives – an error-prone and non-portable practice (e.g. JAX pmap [\[4\]](#page-12-5)). Despite their significant success in research and production, such tools couple the ML model

code (XLA [\[15\]](#page-13-3), Triton [\[59\]](#page-16-2), OpenXLA [\[38\]](#page-14-3)) and the partitioning information together by requiring internal sharding annotations, making it difficult to change the parallelization strategies when the underlying system configuration changes. They also feature no support for incremental composition of various strategies and intermediate feedback to users ahead of actual compilation and profiling – a timeconsuming process in a performance engineer's workflow.

The complexity of partitioning for end-users has motivated research on automated partitioning tools [\[2,](#page-12-6) [24,](#page-13-4) [51,](#page-15-2) [61,](#page-16-3) [65,](#page-16-4)[71\]](#page-16-5). These tools face different challenges: interpretability, predictability, and scalability; making them risky to use for large models where sub-optimal partitioning is costly.

PartIR takes the stance that an incremental partitioner that composes manual and automatic partitioning tactics, provides cost estimates after every applied tactic, offers better control over the sharding of ML programs, reduces the need for model-internal sharding annotations, de-risks automatic partitioning, and makes partitioning an easier task.

1.1 Motivation and key design principles

- Composable sharding strategies: Large NNs use a mix of sharding strategies to maximize their hardware utilization. This can be as simple as applying batch (data) parallelism and model parallelism (e.g., Megatron [\[54\]](#page-15-3) parameter sharding) or a complicated mix of data, possibly model, and optimizer sharding composed together [\[11,](#page-12-3) [20,](#page-13-2) [35,](#page-14-4) [70\]](#page-16-6).
- Verifiable sharding strategies: Each known sharding strategy introduces a verifiable number of MPI-style communication collectives in the ML program and expects a certain runtime behavior. For example, with batch parallelism, we expect one all-reduce collective per parameter and a reduction in per-device flops approximately equal to the batch parallelism factor. Providing this information back to the user allows them to confirm if their sharding strategy implementation is correct, even before compiling their code.

[∗]Equal contribution, authors in alphabetical order. Correspondence to: <dvytin@google.com>

[†]Work done while at Google DeepMind.

- Decoupling model code and sharding strategies: Baking complex sharding strategies in the model makes the resulting artifact difficult to test and maintain while distracting ML engineers with system details; this can be mitigated by decoupling the sharding strategies from the model code, with the extra advantage of making the sharding strategy generalizable to various deployment configurations.
- Native support for composing automated tools: A system that combines both manual and automated tools benefits from a predetermined, well-known sharding strategy manually inserted by an expert, and an automated one [\[2,](#page-12-6) [51,](#page-15-2) [71\]](#page-16-5) to discover unknown sharding strategies. It is particularly useful for experimental models with unknown optimal sharding or for partitioning a fine-tuning model built on top of a foundational model.

We designed PartIR as an MLIR-based compiler [\[31\]](#page-14-5). It separates the partitioning stack from the downstream compiler (e.g., XLA) into external MLIR-based rewriting passes operating on the StableHLO [\[39\]](#page-14-6) dialect, the MLIR encoding of XLA HLO [\[15\]](#page-13-3). This design allowed us to develop the partitioner independently of the downstream compiler and to provide an interface to the high-level libraries (e.g., automatic partitioning) and the JAX-level APIs.

PartIR fully separates the model implementation from its partitioning, allowing ML engineers to focus on building models that outlive the partitioning strategies, without concerns of if and how they need to be partitioned. As an MLIR-based compiler, PartIR could be used for any frontend (Tensorflow, PyTorch, JAX)^{[1](#page-1-0)} or any SPMD backend (XLA, OpenXLA), delegating hardware-specific code generation and execution to the underlying compiler and runtime.

PartIR is built with incrementality and predictability in mind - the user expresses the sharding strategies using sequences of PartIR tactics that we refer to as a schedule. These tactics can never undo sharding decisions introduced by previous tactics in the same schedule and can invoke manual or automatic partitioning. These sharding decisions are translated through PartIR's stack to device-local code that makes communication collectives explicit and verifiable. PartIR provides an analytical simulator for debugging and automated tools that take the hardware description, the inserted collectives, and the model to provide performance and memory estimates of the applied sharding.

1.2 Contributions

To summarize, our main contributions are:

• The overall design of a partitioner system that allows users to compose SPMD sharding strategies incrementally via a schedule [\(3\)](#page-4-0) and decouples the model from its

partitioning to make it possible to step-by-step debug and compose manual or automated sharding decisions.

- A compiler stack [\(4\)](#page-4-1) that exposes tiling and replication actions as a compiler API to be targeted by high-level manual tactics or automated tools. The most important dialects in our stack are (i) PartIR:Core [\(5\)](#page-5-0), which introduces functional tiling and reduction loops on top of an array IR (e.g., StableHLO) that can be given sequential semantics (for a reference implementation) or parallel semantics (for SPMD lowering); and (ii) PartIR:HLO [\(6\)](#page-7-0), which offers a device-local view of the SPMD computation and high-level collective communication primitives. In addition, we have formally proved the correctness of lowering PartIR:Core to SPMD code.
- A pass to propagate partitioning decisions across a module [\(5.2.2\)](#page-6-0), based on linear algebra homomorphisms (LAHs). Propagation in PartIR does not rely on costbased heuristics. The incrementality/ordering of tactics compensates for the internal absence of heuristics and keeps the propagation logic simple. Propagation is implemented as a set of rewrites at the PartIR:Core level that introduce loops expressing these LAHs. The rewriting logic is generic and shared across all tensor ops, simply by querying a centralized registry containing every tensor op's behavior in terms of LAHs.
- An evaluation of PartIR for predictability and debugability [\(7.3\)](#page-9-0), composability across manual or automatic tactics [\(7.3.1\)](#page-9-1), performance of partitioned code [\(7.2\)](#page-8-0), value of incrementality for reducing the number of manual decisions [\(7.4\)](#page-9-2), and compile-time overhead [\(7.5\)](#page-10-0).

PartIR is actively used for scaling a wide range of machine learning models in research [\[6,](#page-12-7) [7,](#page-12-8) [13,](#page-13-5) [23,](#page-13-6) [52,](#page-15-4) [69\]](#page-16-7)

2 Background

We give an overview here of a few fundamental concepts that we will keep referring to throughout this work.

2.1 Device meshes

Distributed execution of large tensor programs employs the concept of a mesh, exposed in ML frameworks (e.g., in jax.sharding.mesh). For our purposes, a mesh is an ndimensional array with named axes that offers a logical view of the available devices. We may view a system of 16 devices as a 2D mesh $\{a:2,b:8\}$; or as 3D mesh $\{a:2,b:2,c:4\}$; or just as a 1D mesh $\{a:16\}$ among many others. The mesh structures used in practice usually reflect the underlying system's communication topology to make reasoning about performance easier and better utilize the fastest networks. For example, consider a cluster of 4 servers with 8 GPUs each,

 1 ¹We only present the APIs for JAX since it is our users' tool of choice.

Figure 1: Batch (N) and model (M) parallelism. On the left, the communication along the M axis (e.g., Megatron's [\[54\]](#page-15-3) activation reductions). On the right, the communication along the N axis (e.g., gradient reductions). Each device parameter shard is color-coded; notably, all devices along the batch axis hold the same shard.

Figure 2: Batch (top) vs. Z3/FSDP parallelism (bottom), assuming two devices. In Z3, the parameters are all-gathered before their use, and their gradients are reduced-scattered before being used to update the local parameter shards.

connected through a fast interconnect network [\[36\]](#page-14-7) within a server, but slower Ethernet connections across servers. One may view this system as a $\{x:4, y:8\}$ system so that communication along devices that span each axis of the mesh happens exclusively on one of the two networks.

2.2 Parallelism strategies

Large-scale NN training is usually performed using a limited set of parallelism strategies:

Batch parallelism (BP) The input batch is sharded across the devices while the model parameters and optimizer state are replicated. We expect to see one AllReduce operation per parameter in the backward pass.

Model parallelism (MP) The model parameters are sharded across the devices – for example in Megatron sharding for Transformer models [\[30,](#page-14-8) [35,](#page-14-4) [54\]](#page-15-3), 2 AllReduce operations (on activation tensors) are introduced per Transformer layer (and 2 more for its backward pass).

Optimizer sharding The optimizer state is sharded to reduce peak-memory. Two popular variants exist: ZeRO2 (Z2) that additionally partitions the parameter gradients, and ZeRO3 (Z3) that further partitions the parameters [\[46,](#page-15-5)[48,](#page-15-6)[66\]](#page-16-8). This paper uses an SPMD-oriented variant that shards all parameters, also known as fully-sharded data parallelism (FSDP) [\[70\]](#page-16-6). From a communication perspective, Z3 introduces AllGather whenever the parameters are needed (once in forward and once in backward pass for every parameter), but has the advantage that the full parameters only live on the device briefly, just before they are used. Correspondingly, in the backward pass, the gradients for the parameters are not reduced; they are rather reduce-scattered across the devices – a cheaper operation. The optimizer is then also sharded and uses the gradient shards and parameter/optimizer shards to update the parameter shards. Figure [2](#page-2-0) gives a simplified view of a training step with batch and Z3 parallelism.

The aforementioned partitioning strategies can be sequentially combined to span one or multiple axes of the device mesh. For example, Figure [1](#page-2-1) illustrates partitioning over such a 2D mesh with data parallelism over one axis and model parallelism over the other. For training large models, multiple strategies are composed, e.g., $BP + MP + Z3$ [\[35,](#page-14-4) [44\]](#page-14-0). Beyond these basic strategies, there exist many others, such as activation sharding after model parallelism [\[30,](#page-14-8)[64\]](#page-16-9), or multi-query sharding techniques in Transformers [\[43\]](#page-14-9). We have implemented and verified (in terms of expected collectives) many of these combinations in PartIR.

Moreover, the PartIR incremental design helps verify that each strategy was applied correctly, as the user can inspect the collectives and estimated performance after each strategy. Some schedules (notably FSDP) rely on prioritizing some sharding decisions over others (Section [5.2.3\)](#page-7-1) – a natural property of incremental partitioning in PartIR.

2.3 Strategies as program transforms

Let us now inspect how the outlined partitioning strategies work in practice. For that, we consider a short JAX [\[4\]](#page-12-5) pro-gram composed of two matrix multiplications^{[2](#page-2-2)}:

 $^2\!$ For simplicity, we do not show a full training step with back-propagation and optimizer code, just a feed-forward function. We even skip the elementwise non-linear operators, as they are trivial to partition.

```
def f(x, w1, w2):
  return (x \otimes w1) \otimes w2y = jax. jit(f)(input, w1, w2) # Trace, compile, and run.Listing 1: A matmul chain in JAX.
```
The jax.jit() function extracts a representation of the Python function that can be converted to XLA HLO [\[15\]](#page-13-3) and compiled for a specific backend. As an intermediate step, JAX represents the program using the StableHLO [\[31\]](#page-14-5) MLIR dialect, which in this case looks as follows^{[3](#page-3-0)}:

```
func \mathbb{Q}main(\mathcal{X}x: tensor <(256 x 8 x f 32 >, \mathcal{X}w1:tensor <8 x16xf32 >, %w2 : tensor <(16 x8xf32 >) {
   %x1 = matmul(%x,  %w1) : tensor<256x16xf32><br>%x2 = matmul(%x1, %w2) : tensor<256x8xf32>
  return %x2 : tensor <256 x8xf32 > }
```
Listing 2: An unpartitioned matmul chain.

Note that each value is annotated with a type, e.g., %x1 = ...: tensor<256x16xf32>, denoting an array of shape [256,8] and a float32 element type.

Assume we are given a 2D mesh ${B : 4, M : 2}$ to execute this program – what kind of parallelization strategy should we use?

Batch (data) parallelism One strategy is to partition the first (256-sized) dimension of input χ across axis B, observing that the program is a pure "map" over that dimension:

```
func @main %x: tensor 64x8xf32, %u1:tensor <8x16xf32>, %w2: tensor <16x8xf32>)<br>attributes {mesh={"B":4, "M":2}} {
   %x1 = \text{matmul}(\frac{x}{x}, \frac{y}{w1}): tensor <64x16xf32><br>%x2 = \text{matmul}(\frac{y}{x1}, \frac{y}{w2}): tensor <64x8xf32>
   \sqrt[6]{x2} = matmul (\sqrt[6]{x1}, \sqrt[6]{w2}) :
   return \, x2 : tensor < 64x8xf32>
```
Listing 3: Data-parallel matmul chain.

The resulting device-local program above takes a first argument of smaller shape 64x8 since each device acts in parallel on a slice of %x determined by the device coordinate along axis B . At the same time, the shape of parameters $%$ w1 and %w2 remains constant across all devices (due to replication).

Adding model parallelism If, on top of BP, we partition the parameter $\frac{m}{2}$ on $\dim = 1$ and $\frac{m}{2}$ on $\dim = 0$ along axis M , then each device along axis B may perform a smaller multiplication with a different parameter shard:

```
func @main(%x: tensor<64x8xf32>, %w1: tensor<8x<mark>8</mark>xf32>,
   %w2: tensor<8x8xf32>) attributes ... {
  x_1 = matmul(x, x_0) : tensor <64x8xf32>
  \chi_{x2} = matmul (\chi_{x1}, \chi_{w2}) : tensor <64x8xf32>
  \sqrt[6]{x3} = all_reduce <"M"> \sqrt[6]{x2} : tensor <64x8xf32>
  return %x3 : tensor <64 x8xf32 > }
```
Listing 4: Data-parallel and sharded matmul chain.

The first matmul is a map over the second dimension of %w1, so no special care is necessary. We need only to remember that %x1 is partitioned along its second dimension. For the

second matmul, we observe that both of its operands are partitioned along the contracting dimensions. Hence, we can recover the original program semantics by inserting a final all_reduce operation across axis M . This sharding of pairs of matrix multiplications is the essence of the Megatron sharding in Transformers [\[54\]](#page-15-3).

Adding fully sharded parameters Notice that the parameters are only sharded on axis M (but not B) in Listing [5.](#page-3-1) We could modify the function to shard them further on dimensions 0 and 1, respectively, but we would need to insert two all gather operations right before they are needed in the matrix multiplication:

```
func @main(%x: tensor<64x8xf32>, %w1:
      tensor<2x8xf32>, %w2: tensor<8x2xf32>)
      \text{attributes } \{\text{mesh} = {\texttt{['B":4, "M":2]}} \}%w1g = all_gather [{{'}}"B", {}_{ } {}_{ }  \} \%w1 : tensor <8x8xf32>
   %x1 = matmul(%x, %w1g) : tensor<64x8xf32><br>%w2g = all_gather [{}, {"B"}] %w2 : tensor<8x8xf32>
  x^2 = \text{matmul}(\sqrt[n]{x1}, \sqrt[n]{x2g}) : tensor <64x8xf32>
  %x3 = all_reduce <"M"> %x2 : tensor <64 x8xf32 >
  return %x3 : tensor <64 x8xf32 > }
```
Listing 5: Data-parallel and fully sharded matmul chain.

These operations gather the shards on the corresponding dimensions. This sharding of parameters, after batch parallelism, is the essence of (SPMD) Z3 sharding [\[46\]](#page-15-5). Note that the parameters are only gathered before use, reducing the peak memory requirements.

Of course, more complex shardings are possible on top of the aforementioned chain of strategies. For example, the input and output activation (%x and the return value) may be additionally sharded on the model axis M . Such a sharding will convert the all_reduce to an reduce_scatter and introduce an all_gather on the input %x before using it in the first matmul. We omit the MLIR code for this transformation (this, in effect, is the ES strategy in Section [7.](#page-8-1))

The sequence of examples above highlights that (i) popular sharding strategies do compose; (ii) by following linear algebraic reasoning, a model can be partitioned just by sharding its inputs and parameters, and sometimes internal operations, see Section [8;](#page-11-0) (iii) it suffices to utilize information about the operations' parallel and contracting dimensions. In the rest of the paper, we show how to express these strategies through compiler actions that enable a semantics-preserving rewrite of an initial unpartitioned program (as in Listing [2\)](#page-3-2) into a device-local program (as in Listings [3](#page-3-3) to [5\)](#page-3-1).

A note on scale Although the illustrating example was small, a typical ML model contains thousands of tensor operations (e.g., dot-products, convolutions, gather and scatter ops, and more) and control flow (e.g., conditionals and loops). A full training step, including back-propagation and optimizer, can reach 10-100k operations and have thousands of multi-dimensional array arguments for model parameters and optimizer state. A good API should not burden the user with a decision per operation or function argument.

³StableHLO does not feature a matmul op, and represents it using a dot_general op. We use matmul as syntactic sugar for terser presentation.

3 A schedule is all you need

PartIR exposes a schedule-like API, inspired by work in kernel-generating DSLs [\[9,](#page-12-9) [16,](#page-13-7) [29,](#page-14-10) [45,](#page-15-7) [68\]](#page-16-10). This API allows users to compose partitioning strategies incrementally. In PartIR, a schedule is a sequence of manual or automatic tactics. For example, to achieve the final sharding of f (Listing [1\)](#page-3-4) appearing in Listing [5,](#page-3-1) a JAX user would write:

```
# 1. Arrange devices in a BxM mesh.
mesh = maps.mesh(device_array, ("B", "M"))
# 2. Define sharding strategies as series of tactics.
BP = ManualPartition ({^{\{\prime\prime}}x^{\prime\prime}:0}, axis="B")
MP = ManualPartition({"w1":1}, axis="M")<br>Z3 = ManualPartition({"w1":0, "w2":1}, axis="B")
schedule = [BP, MP, Z3]# 3. Partition and get metadata & distributed function.
dist_fn, metadata = partir.jit (f, mesh, schedule)
```
Listing 6: Partitioning strategies as a series of tactics in a schedule.

The first tactic BP partitions the first argument "x" on dimension 0 and across axis "B"; yielding batch parallelism (Listing [3\)](#page-3-3). The second tactic MP partitions input w1 on dimension 1. The compiler will identify that this action is sharding the contracting dimension of a matmul and will shard w2 on dimension 0 through a process we call propagation invoked at the end of every tactic (Listing [4\)](#page-3-5). The final tactic Z3 shards the parameters on the remaining available dimensions and axis B (Listing [5\)](#page-3-1). The schedule is finally passed to partir.jit together with the function to partition and the device mesh. partir.jit works like jax.jit, but injects the PartIR partitioning stack before compilation.

Even though we present JAX API examples, PartIR operates over StableHLO, making it frontend- (e.g., JAX, PyTorch, TensorFlow) and a backend- (e.g., XLA, CUDA, OpenXLA) agnostic, as long as they produce and consume StableHLO.

partir.jit returns a partitioned module exposed as a Python callable ready to be called with JAX sharded arrays and executed on the devices of the mesh. Additionally, PartIR produces various metadata that includes a sharding specification of the function inputs and outputs produced by PartIR, and cost estimates (e.g., collective communication breakdown by type and simulation results) recorded after every tactic in the schedule. Dumping the intermediate modules after every tactic is also very common for debugging.

Mixing automatic and manual tactics PartIR exposes an AutomaticPartition tactic that operates on one or more mesh axes and can be composed with other manual tactics. For example, users could use a manual tactic to introduce batch parallelism manually, and rely on an automatic tactic to discover partitioning along the second axis "M":

```
BP = ManualPartition({{\cdot}''x":0}, axis={"B"})AutoMP = AutomaticPartition (axis="M'
part_fn, _ = partir.jit (fn, mesh, [BP, AutoMP])
```
Listing 7: A schedule consisting of manual and automation tactics.

The AutomaticPartition is an interface for any optimization algorithm. We implemented a Monte Carlo tree search

Figure 3: PartIR partitioning stack, built on top of MLIR, so it supports layering of new operators on top of existing ones – hence, we use "+" to signify the introduction of new operators, and "-" to signify that certain operators have now become illegal.

for discovering partitioning strategies [\[2,](#page-12-6) [51\]](#page-15-2), using a cost model that seeks runtime improvement and penalizes models that exceed device memory limits.

What is essential for composability is that both manual and automatic tactics issue sequences of (the very same) lower-level PartIR compiler actions that either (i) shard a value dimension along an axis or (ii) explicitly keep a value unpartitionable across a mesh axis, or (iii) propagate sharding information across a module. For example, the schedule in Listing [6](#page-4-2) generates a sequence of 7 PartIR actions:

```
tile <%x, 0, "B" >; propagate; // BP tactic
tile < %w1,1, "M" >; propagate ; // MP tactic
tile < %w1,0, "B" >; tile < %w2,1, "B" >; propagate ; // Z3
```
In what follows, we focus on the PartIR system architecture, the implementation of actions as program rewrites, and how PartIR eventually generates device-local SPMD code.

4 System architecture

Figure [3](#page-4-3) gives an architectural overview of our system:

- Programs are generated from tracing JAX functions in the MLIR StableHLO dialect, as described in Section [2.3.](#page-2-3)
- Manual or automatic tactics generate sequences of compiler actions that introduce and propagate functional loops and specialized slicing ops, that belong in the PartIR:Core dialect.
- PartIR:Core loops and slices are interpreted as sequential loops in the PartIR:Temporal dialect, whose main use is a reference semantics of PartIR:Core alongside more niche applications like automatic microbatching transforms. We do not expand on this dialect further as we focus on SPMD in this paper.

• PartIR:Core loops and slices are lowered to the PartIR:HLO dialect generating device-local collective communication ops. The collectives at PartIR:HLO refer to mesh axes that make their IR encoding independent of the total number of devices in the mesh (as opposed to collectives in StableHLO and XLA HLO that directly reference groups of logical device IDs), and makes it easy to reason about and fuse (Section [6\)](#page-7-0). As a result, we implemented our simulation at that level. To export, we lower any custom high-level PartIR:HLO ops to StableHLO computations and hand over the module to XLA for compilation.

As Figure [3](#page-4-3) shows, our architecture and separation of dialects allow us to implement the right rewrites at the right level of abstraction and to also independently test various components of the partitioner. For example, PartIR:Core is unaware of SPMD execution, and its rewrite axioms remain very simple; this is a separate step from SPMD lowering (a pass that we have additionally proven correct), or the optimization of communication primitives.

5 PartIR:Core

PartIR:Core introduces just two operations on top of the legal operations in StableHLO: (1) a loop op that expresses pure (parallel) loops performing tiling or reductions, and (2) a slice op that extracts a tensor slice based on a loop index. We will directly present these constructs and their semantics as part of describing the PartIR:Core compiler actions.

5.1 Value tiling action

A tiling action tile<%value, dim, axis> creates a loop that in each iteration yields a slice of %value along dimension dim. For example, value tiling %x along dimension 0 and axis "B" from Listing [2](#page-3-2) produces:

```
func \texttt{Qmain} (%x: tensor <256x8xf32>, %w1:
      tensor <8 x16xf32 >, %w2 : tensor <16 x8xf32 >) {
     %xt = loop "B" [#tile <0 >] ( %rB : range <4 >) {
yield ( slice 0 %x [ %rB ])
     } : tensor <256 x8xf32 >
     \%x1 = \text{matmul} (\%xt, \ %w1)\chi_{x2} = matmul (\chi_{x1}, \chi_{w2})return %x2 : tensor <256 x8xf32 > }
```
The loop operation contains two static attributes: (i) a mesh axis ("B") and (ii) an action attribute (#tile<0>). It also accepts a single-argument closure (a region in the MLIR jargon) that represents the loop body: (%rB: range<4>){ ... }. The closure takes as an argument a *range value* (%rB) and performs a tensor computation returning a value of type tensor<64x8xf32>. The range argument %rB plays the role of a loop index given a PartIR-specific range type.

The slice ops consume these loop indices. The meaning of slice 0 %x[%rB] is that it extracts the %rB-th chunk of the tensor %x along dimension 0. The tiling here perfectly

partitions the tensor dimension into 4 equally-sized, contiguous chunks since axis "B" has size 4. Hence, the result of slice has shape 64x8. Furthermore, the value tiling action has replaced %x of type tensor<256x8xf32> with value $% x t$ of the same type – i.e., value tiling is a semantics- and type-preserving local rewrite.

5.2 Propagation action

Value tiling actions create fairly trivial loops making them not particularly interesting. However, they help bootstrap a powerful propagation pass that subsequently creates loops around operations consuming or producing these values and further slices other arguments. This propagation is justified by program equivalences that directly encode linear algebra homomorphisms.

5.2.1 Program equivalences

PartIR propagation is built around program equivalences that involve loop and slice instructions. Figure [4](#page-6-1) presents three admissible program equivalences for a matrix multiplication. The first two rewrite a matrix multiplication as a tiling loop with a smaller multiplication inside. The last one introduces a new form of attribute accompanying the loop, a #sum action attribute. This signifies that the results of each iteration of the loop should be reduced, as we are slicing the operands on their contracting dimension.^{[4](#page-5-1)} These equivalences are justified as linear algebra homomorphisms, with the monoidal structure being stacking for the first two and addition for the last one.

To allow us to implement the rewriting code once and for all, for all operators, we equip PartIR with a tile-mapping registry (TMR) that enables a concise encoding of linear algebra homomorphisms as maps between tiling and reduction attributes. The TMR contains, for every tensor operation with n inputs, a set of specifications of the form

$$
t_1^{\perp},\ldots,t_n^{\perp}\hookrightarrow \sigma_1,\ldots,\sigma_k
$$

where t^\perp stands for an optional tiling action, while σ stands for an arbitrary action (including #sum). StableHLO ops and our loops may return multiple results, hence the generalized form $\sigma_1, \ldots, \sigma_k$. One such specification asserts that a given operation can be rewritten as a loop with action(s) $\sigma_1, \ldots, \sigma_k$ if we slice its operands according to $t_1^{\perp}, \ldots, t_n^{\perp}$ (a missing action implies no slicing).

We give below the entries for matmul (corresponding to the three equivalences from Figure [4\)](#page-6-1) and for an elementwise add operation that, unsurprisingly, asserts that tiling

⁴We assume addition here, but our implementation supports #sum<@f> custom reductions for any associative reduction @f.

```
%t = loop "B" [#tile <\overline{Q}>] (%rB:range <4>) {
   x s = slice 0 x x [rB]\%z = \text{matmul}(\sqrt{2}xs, y)yield %z : tensor <8x8xf32> }
%t = loop "B" [#tile <1>] (%rB: range <4>) {
   %ys = slice <mark>1</mark> %y[%rB]<br>%z = matmul(%x, %ys)
   yield %z : tensor<32x2xf32> }
%t = loop "B" [ #sum] (<math>YrB : range < 4</math>) {%xs = slice <mark>1</mark> %x[%rB]<br>%ys = slice <mark>0</mark> %y[%rB]
   \chi_{z} = matmul (\chi_{xs}, \chi_{ys})
   yield %z : tensor <32x8xf32> }
```
Figure 4: Programs equivalent to $\lambda t = \text{matmul}(\lambda x, \lambda y)$. We assume %x : tensor<32x16xf32> and %y : tensor<16x8xf32>, and a mesh axis "B" of size 4.

its result requires tiling its operands in the same way:

 $TMR(matmul) = \{(\#tile\langle 0 \rangle, \bot) \hookrightarrow \#tile\langle 0 \rangle\}$ ∪ {(⊥,#tile⟨1⟩) ↩→ #tile⟨1⟩} $∪$ {(#tile $(1),$ #tile (0)) \hookrightarrow #sum} TMR(add) = { $(\# \text{tile}\langle d \rangle, \# \text{tile}\langle d \rangle) \hookrightarrow \# \text{tile}\langle d \rangle$ }

It turns out that this abstraction (similar to split annotations [\[40\]](#page-14-11)) is sufficient to capture a wide variety of equivalences, and for substantially more complex ops, e.g. convolutions, scatter and gather, dynamic slices, and reshapes.

5.2.2 Propagation pass

Propagation is a pass that greedily propagates known and partially known information and introduces more loops-based on the linear algebra homomorphisms encoded in the TMR.

Propagation of known information Forward propagation searches for an entry that matches the actions of loops that produce operands of an operation, whereas *backward*^{[5](#page-6-2)} propagation searches for an entry that matches the way the operation result is sliced downstream. For example, assume that the value %x1 in Listing [2](#page-3-2) has been tiled already.

```
func @main %x: tensor <256 x8xf32>, %x1:
     tensor <8 x16xf32 >, %w2 : tensor <16 x8xf32 >) -> ... {
  \sqrt[6]{x1} = matmul (\sqrt[6]{x}, \sqrt[6]{w1})// value tiling
%x1t = loop "B" [#tile <0 >] ( %rB : range <4 >) {
    yield (slice 0 %x1[%rB])
  }
  %x2 = \text{matmul} (<math>%x1t, %w2</math>)return %x2 : tensor <256 x8xf32 > }
```
To propagate tiling forward, we observe that the matmul defining %x2 now takes an operand whose first dimension is tiled, hence the TMR entry $(\# \text{tile} \langle 0 \rangle, \bot) \hookrightarrow \# \text{tile} \langle 0 \rangle$ for matmul matches its operand context. Propagating backward, %x1 is produced by a matmul and is then sliced along

dimension 0, which matches the result of that same TMR entry. As a result, both operations can be rewritten:

```
func @main(%x: ..., %w1: ..., %w2: ...) -> ... {
  // result of backward propagation
  x_1 = \text{loop} "B" [#tile <0>] (%rB: range <4>) {
    yield (\texttt{matmul}(\texttt{slice 0 %x[%rB], %w1})}
  // value tiling
%x1t = loop "B" [#tile <0 >] ( %rB : range <4 >) {
    yield (slice 0 %x1[%rB])
  }
  // result of forward propagation
  %x2 = loop "B" [#tile <0 >] ( %rB : range <4 >) {
    yield (\text{natural}(s)ice 0 x1t[xB], xw2)]
  }
  return %x2 : tensor <256 x8xf32 > }
```
Through propagation, we have arrived at a program where every operation is within a loop context. These loops may be interpreted sequentially in PartIR:Temporal for microbatching or lowered directly to SPMD in PartIR:HLO.

Here is what the fused program looks like:

```
func @main(%x: ..., %w1: ..., %w2: ...) -> ... {
   %r = loop "B" [#tile<0>] (%rB : range<4>) {<br>%xs = slice 0 %x[%rB] : tensor<64x8xf32>
      \texttt{\%x1s} = matmul ( \texttt{\%xs} , \texttt{\%w1)}\chi_{X2s} = matmul (\chi_{X1s}, \chi_{W2})
      yield %x2s : tensor<64x8xf32>
   }
   return \lambdar : tensor <256 x8 x f 32 > }
```
Listing 8: Chained matrix multiplication with a tiling loop.

Inference from partially known information Inference is the process of deducing missing operand value tiling based on a partial match against a TMR entry. Continuing from Listing [8,](#page-6-3) consider value-tiling %w2:

```
func @main(%x: ..., %w1: ..., %w2: ...) -> ... {
  \%w2t = loop "M" [#tile<0>] (\%rb: range<2>) {
    yield (slice 0 \sqrt[3]{x^2} \sqrt[8]{r}b])
  }
%x2 = loop "B" [#tile <0 >] ( %rB : range <4 >) {
    \%xs = slice 0 \%x [\%rB]
     %x1s = matmul(%xs, %w1)<br>%x2s = matmul(%x1s, %w2t)
    yield %x2s
  }
  return %x2 : tensor <256 x8xf32 > }
```
The TMR entry $\#$ tile $\langle 1 \rangle$, $\#$ tile $\langle 0 \rangle$) $\hookrightarrow \#$ sum is a partial match on the operands of the second matmul, since the second operand (%w2t) is already tiled. We can extend it into a full match by value tiling the first operand (%x1s) and then continuing with forward propagation to eventually (after some simplification) arrive at:

```
func @main(%x: ..., %w1: ..., %w2: ...) -> ... {
  \chi_{\text{r}} = loop "B" [#tile <0>] (\chi_{\text{r}}B: range <4>) {
    x2s = loop "M" [#sum] (xN : range <2) {
       %x s = slice 0 %x [%rB] : tensor <64 x 8 x f 32 >%w1s = slice 1 %w1 [%rM] : tensor <8x8xf32>
        %x1ss = matmul(%xs, %w1s) : tensor<64x8xf32><br>%w2s = slice 0 %w2[%rM] : tensor<8x8xf32>
       x2ss = matmul (xx1ss, yw2s): tensor <64x8xf32>
       yield %x2ss : tensor <64 x8xf32 >
    \overline{1}yield %x2s : tensor<64x8xf32>
  \mathbf{r}return %r : tensor <256 x8xf32 > }
```
 5 Not to be confused with NN optimizer back-propagation.

Notice how in that final program, both $\frac{1}{2}$ w1 and $\frac{1}{2}$ w2 end up only used sliced across axis "M", even though only %w2 was explicitly value-tiled.

Inference is of paramount practical importance in ML programs. For example, the optimizer state in a training step function can be left to be partitioned as the parameters are by inference since parameters and optimizer state flow to element-wise operations that express the parameter update.

5.2.3 Conflicts during propagation

In some situations, it is impossible to propagate the tiling. E.g. when a loop over some axis would need to be inserted in the scope of an existing loop over the same axis, which we forbid as nested loops along the same axis cannot be mapped to meshes, or when multiple (partial) TMR matches are found — a situation that we refer to as a conflict. Consider:

```
func @main(%x: ..., %w1: ...) -> ... {<br>%xt = loop "B" [#tile<0>] (%rB: range<4>) {
      yield (slice 0 %x[%rB])
     }
%w1t = loop "B" [#tile <1 >] ( %rB : range <4 >) {
       yield (slice 1 %w1[%rB])
     }<br>%x1 = matmul(%xt, %w1t) ...
```
Here, the operands of the matmul defining %x1 are tiled in a way that matches two TMR entries: $(\# \text{tile} \langle 0 \rangle, \bot) \hookrightarrow$ $\#$ tile⟨0⟩ and $(\bot, \#$ tile⟨1⟩ $\hookrightarrow \#$ tile⟨1⟩.

PartIR will not attempt to resolve conflicts automatically. Instead, the canonical solution is to perform the rewriting incrementally. For example, performing value tiling on %x and propagating that choice before value tiling %w1 would yield the following program:

```
func @main(%x:..., %w1: ...) -> ... {<br>"%w1t = loop "B" [#tile<1>] (%rB: range<4>) {
       yield (slice 1 %w1[%rB])
    }
// below is result of propagation after tiling %x
%r = loop "B" [#tile <0 >] ( %rB : range <4 >) {
%xs = slice 0 %x [ %rB ] : tensor <64 x8xf32 >
        \sqrt[n]{x1s} = matmul (\sqrt[n]{x}s, \sqrt[n]{w1t})...
```
At this point the TMR entry $(\perp, \# \text{tile} \langle 1 \rangle) \hookrightarrow \# \text{tile} \langle 1 \rangle$ matches the definition of %x1s again. Alas, the operation in hand is already nested inside a loop over axis "B" and no further propagation is possible – creating a doubly-nested loop over "B" is invalid. This prioritization of BP over subsequent parameter sharding is exactly what is needed for the ZeRO [\[46\]](#page-15-5) sharding strategies.

The prioritization of rewrites, happening naturally at the boundaries of PartIR manual tactics makes conflicts be fairly rare, and as a result dramatically reduces the need for many internal sharding decisions (but does not entirely remove their need, see Section [8.](#page-11-0))

5.2.4 PartIR:core actions and multiple axes

Our tiling and propagation actions naturally extend to loop nests over multiple axes, see Appendix [B.](#page-22-0)

6 SPMD code generation

PartIR:HLO expresses per-device SPMD computation. It includes StableHLO tensor and control flow ops, but introduces specialized collective ops for communication, which unlike their low-level HLO counterparts, operate on mesh axes, i.e. communication spans across device groups defined by a different set of coordinates along these axes. We now introduce the collectives included in our implementation with examples in Listing [9:](#page-8-2)

- An all_reduce (line 2) reduces arrays along one or more mesh axes according to some reduction function (in the example @red_fn), replicating the tensor in each device.
- An all_slice (lines 3 and 4) includes an array of axes per dimension – the axes in which each dimension is sliced. In line 2, the first dimension is sliced along "x1", the second dimension is not sliced, and the third dimension is sliced along "x2". In the result array, each dimension size is divided by the size of (the product of) the slicing axes in this dimension – each device holds a slice of the original array based on the coordinate tuple along the slicing axes.
- An all_gather (line 5) is dual to all_slice. Its operand is gathered along the gathering axes in each dimension. Each dimension size of the result is multiplied by (the product of) the gathering axes in this dimension. Figure [5](#page-8-3) demonstrates the semantics of all_slice and all_gather.

Patterns such as all_slice(all_gather(%x)) or all_slice(all_reduce($\frac{N}{x}$)) are fused into all_to_all and reduce_scatter(%x), respectively, by a PartIR:HLO pass.

- A reduce_scatter (line 6) effectively is the fusion of an all_reduce followed by all_slice. In particular, this example is the fusion of collectives in lines 2 and 3.
- An all_to_all (line 7) corresponds to a fusion of an all_gather along a dimension (0) followed by all_slice over the same sequence of axes in another dimension (1).

6.1 From PartIR:Core to PartIR:HLO

Lowering of PartIR:Core to PartIR:HLO is a type-preserving transformation that transforms (i) slice ops to all_slice collectives, and (ii) inserts all_gather or all_reduce collectives in the results of tiling loops. We demonstrate this process with an example:

```
func @main(%x: t < 256 x 8 >, %w1: t < 8 x 16 >, %w2: t < 16 x 8 >) {
   %r = loop "B" [#tile <0 >] ( %rB : range <4 >) {
%x2s = loop "M" [ #sum ] ( %rM : range <2 >) {
         %xs = slice 0 %x [%rB] : tensor <64x8xf32>
```

```
// Below, assume mesh: {x1 : 2, x2 : 4, x3 : 8}%result = all_reduce < @red_fn > < "x1", "x2"> %operand : tensor <16x500x40xf32> -> tensor <16x500x40xf32>
3 %result = all_slice [{"x1"}, {} , {"x2"}] %operand : tensor <16x500x40xf32 > -> tensor <8x500x10xf32 >
4 %result = all_slice [{"x1, "x3"}, {} , {"x2"}] %operand : tensor <16x500x40xf32 > -> tensor <1x500x10xf32 >
5 %result = all_gather [{"x1"}, {"x3"}, {}] %operand : tensor <8x10x16xf32 > -> tensor <16x80x16xf32 >
%result = reduce_scatter<@red_fn> [{"x1"}, {}, {"x2"}] %operand : tensor <16x500x40xf32> -> tensor <8x500x10xf32>
%result = all_to_all {0 -> 1} <"x1", "x2"> %operand : tensor <16x32xf32> ->s tensor <128x4xf32>
```
Listing 9: PartIR:HLO collectives by example. Relevant dimensions and attributes (e.g. slicing or gathering axes) have been highlighted.

Figure 5: Demonstration of sequences of all_slice and all_gather collectives on a mesh ${x:2, y:2}$. Top: all devices hold the same 2D array; bottom: data is sliced row-ise along axis "y"; right: data is further sliced column-wise along axis "x". In each case we give the device-local tensor types.

```
%w1s = slice 1 %w1 [%rM] : tensor <8x8xf32>
      %x1ss = matmul(%xs, %w1s) : tensor<64x8xf32><br>%w2s = slice 0 %w2[%rM] : tensor<8x8xf32>
     x2ss = \text{matmul} (x1ss, yw2s) : tensor <64x8xf32>
     yield %x2ss : tensor <64 x8xf32 >
  }
  yield %x2s : tensor <64x8xf32>
}
%s = loop "B" [#tile <0>] (%rB: range <4>) {
    %rs = slice 0 %r[%rB] : tensor<64x8xf32>%xs = slice 0 %s[%rB] : tensor<64x8xf32>
    \%w = add \text{ %}xs \text{ % }xs : tensor <64 x8 xf32 >
}
return Xs : tensor <256x8xf32>
```
Mechanically following the lowering rules outlined in the beginning of this section gives:

```
func @main(%x: t < 256 x 8 >, %w1: t < 8x16 >, %w2: t < 16 x 8 >) {
  // First loop nest.
  %xs = all_slice [{"B"}, {}] %x : tensor <64 x8xf32>
  %w1s = all_slice [{} ,{"M"}] %w1 : tensor <8 x8xf32 >
  x1ss = \text{matmul} (xss, xus): tensor <64x8xf32>
  %w2s = all\_slice [{-M"}, {}_{y2}: tensor <8x8xf32x2ss = \text{matmul} (x1ss, x2s) : tensor <64 x8 x f 32>
  x2s = a11_reduce <i>ym</i>" > <i>x2ss</i> : tensor <math>64x8xf32</math>x = all_gather [{T^B}^n, {}] x2s : tensor <256x8xf32// Second loop nest.
  %rs = all\_slice [{ "B" },  {}] %r : tensor <64x8xf32>
  %xs = all_slice [{P_B}^n], {P_J}^n _{xx} : tensor <64x8xf32>
  \sqrt[6]{w} = add \sqrt[6]{xs} \sqrt[6]{xs} : tensor <64x8xf32>
  %s = all_gather [{{"B}"}, { } {}] %w : tensor <256 x8xf32>
  return %s : tensor <256 x8xf32 > }
```
The all_slice(all_gather)(%xs2) in this example is fused away. Additionally, the function arguments used by all_slice ops and the results produced by all_gathers are converted to device-local arrays:

```
func @main (xs: tensor <64x8xf32>, %x1s:tensor <8 x8xf32 > , %w2s : tensor <8 x8xf32 >) {
  // First loop nest.
  x1ss = \text{natural} (xss, xus) : tensor <64x8xf32>
  x2ss = \text{matmul} (x1ss, yw2s): tensor <64x8xf32>
  x2s = a11_reduce <"M"> x2ss: tensor <64x8xf32>
  // Second loop nest.
  \%w = add \%x2s \%xs : tensor <64x8xf32>
  return %w : tensor <64x8xf32> }
```
Simulation is performed on PartIR:HLO programs, after we have applied collective ops optimizations and additional rewrites to enable compute-communication overlap [\[64\]](#page-16-9).

7 Evaluation

PartIR is a partitioning stack for users who care about performance, expressibility, and predictability. Hence, we evaluate the following claims about PartIR: (1) its partitioning of models achieves comparable performance to the SOTA tool, across different systems [\(7.2\)](#page-8-0); (2) it is predictable on a variety of models [\(7.3\)](#page-9-0); (3) it effectively composes tactics, manual and automated [\(7.3.1\)](#page-9-1); (4) its propagation reduces the number of decisions a user makes, and resolves conflicts [\(7.4\)](#page-9-2); and (5) its overhead is small compared to compilation time [\(7.5\)](#page-10-0).

7.1 Benchmarking setup

We use the following set of models as case studies: T32 a 32 layers, 5B parameters Transformer model based on Chinchilla [\[20\]](#page-13-2); T48 a 48 layers, 32B parameters variant of T32; I32T is a 32 layers inference Transformer model [\[43,](#page-14-9)[62\]](#page-16-11) with key-value caching; U-Net is a model used in the reverse process of a diffusion model [\[19\]](#page-13-8); GNS is a Graph Network Simulator [\[49\]](#page-15-8) model for molecular property prediction [\[14\]](#page-13-9).

When measuring runtime, we perform a warmup step and then report the measurements of 10 restarts, each performing a 100 training or inference steps depending on the model; we repeat this process three times and report the average. All experiments used TPUv3 [\[12\]](#page-12-0) and Nvidia A100 [\[37\]](#page-14-12); we refer to them as TPU and GPU, respectively. The models and hardware specifications are reported in Appendix [A.](#page-17-0)

7.2 Partitioned models matches SOTA

We validated that the performance of models partitioned with PartIR is comparable to that of GSPMD [\[67\]](#page-16-1) in terms of

		MFU(%)		HBM (GB)			
Mesh	Size	PartIR	GSPMD	PartIR	GSPMD		
16x2 TPU	5B	58.5	58.3	14.38	14.38		
$32x4$ TPU	32B	52.3	52.2	14.48	14.48		
8x2 GPU	5B	42.2.	42.9	27.02	26.73		

Table 1: PartIR and GSPMD comparison in terms of MFU (higher is better) and HBM usage (lower is better) on GPUs and TPUs.

Model	Schedule	AG	AR	RS	A2A
T32	ВP	Ω	290	Ω	0
	$BP+MP$	Ω	418	∩	0
	$BP+MP+Z2$	129	289	129	0
	$BP+MP+Z3$	259	289	129	0
	$BP+MP+Z3+EMB$	515	354	257	0
	MP	Ω	128	Ω	0
	EMB	256	193	128	0
IT32	ВP	Ω	Ω	Ω	0
	$BP+MP$	Ω	98304	0	0
	$BP+MP+MO$	64	98304	Ω	98240
	MP	Ω	98304	Ω	θ
UNet	ВP	Ω	503	Ω	Ω
	$BP+Z2$	517	2	501	0
	$BP+Z3$	799	2	501	0
GNS	ES	Ω	423	θ	θ

Table 2: Number of collectives introduced by different schedules. AG: AllGather, AR: AllReduce, RS: ReduceScatter, A2A: All2All.

Model FLOPS Utilization (MFU) [\[11\]](#page-12-3) and High-Bandwidth Memory (HBM) usage, as reported by the XLA compiler, by training the T32 (5B) and T48 (48B) models with both PartIR and GSPMD. For the T32 model, we tested two configurations: 1) partitioned over 32 TPUs and 2) over 16 GPUs, while the T48 partitioned over 128 TPUs. In the PartIR version, we partitioned both models using a schedule of four tactics (BP+MP+Z3+EMB) and relied on equivalent expert sharding annotations for the GSPMD version. The results in Table [1](#page-9-3) show that the performance of PartIR is on par with that of GSPMD, with negligible improvements in MFU ($\approx 1\%$) in TPU configurations and a small regression ($\approx 2\%$) in the GPU configuration. The HBM usage are comparable too with a regression of $\approx 1\%$ on GPUs.

7.3 Composability and predictability

We demonstrate how PartIR users can compose well-known strategies using manual tactics while getting the expected communication collectives (from the respective papers), as reported after every tactic is applied. We partitioned four different models with different schedules and inspected the resulting number of collectives, shown in Table [2.](#page-9-4)

T32 has 289 parameter tensors (9 for each block + embeddings). With batch parallelism, we expect one AR for each parameter gradient tensor and one AR for the loss value. The resulting 290 ARs add up with the 4 ARs per layer that Megatron [\[55\]](#page-15-9) requires when composing both strategies together. Both Z2 and Z3 [\[46\]](#page-15-5) partition parameter gradients and optimizer states along the batch axis (of embeddings and four-parameter tensors per layer in this experiment), resulting in 129 of the existing ARs becoming RSs, and the introduction of one or two AG per parameter tensor in the case of Z2 or Z3, respectively. The embedding partition strategy (EMB) partitions the embedding tensor along the d_model dimension, which has the effect of partitioning activations, which in turn helps leverage collective-compute overlapping [\[64\]](#page-16-9). The reasoning is similar for IT32 and UNet. Note that IT32 is an inference-only benchmark and does not require any AR for batch parallelism. Moreover, the serving loop in IT32 greatly amplifies the number of collectives. Multi-query sharding (MQ) [\[43\]](#page-14-9) over the batch axis introduces an AR and two A2A per layer, except for the final loop, which requires an extra AG.

Finally, GNS is made of nodes connected by edges; we partitioned it using edge sharding (ES) [\[18\]](#page-13-10), which partitions the GNS's edges, creating subgraphs around the edges and distributes them to devices in the network while replicating the associated GNS's nodes. Every message passing and propagation through the GNS introduces a collective to communicate updates from neighbors in the GNS's graph. Thus, we expect 2 AR per messaging passing (24) through each MLP layer (5) of every node and one for the global feature aggregator, the molecular GNS has an additional 2 AR for the graph encoder and one final one at the decoder.

7.3.1 Partial or full automation in schedules

PartIR users may not wish to partition their models manually, and not every model architecture has a well-studied set of partitioning strategies. Thus, users may explore different degrees of automation: fully manual, partially automatic, or fully automatic. Figure [6](#page-10-1) shows the actual runtime results of combining manual and automatic tactics and using them to partition the models for 32 TPU devices.

Using automatic partition can alleviate the burden of manually partitioning T32, where AllAuto results in a partition with comparable performance to a fully manual schedule. While combining manual with automatic partition gives us performance improvements for UNet and GNS, it can also come with a performance penalty: e.g., BP+Auto+Z3 in T32 results in slower runtimes than the fully manual schedule.

7.4 Resolving conflicts with incrementality

We show the importance of incrementality as a solution for compiler-internal conflicts in Fig. [7.](#page-10-2) We compared PartIR against PartIR-st (Single Tactic), which amalgamates all tactics of a schedule into a single tactic (i.e., no propagation in between tactics); GSPMD, with expert-defined sharding

Figure 6: Training runtime (lower is better) on a 8x4 TPU mesh.

Figure 7: Relative slowdown compared to PartIR (higher is worse) for UNet partitioned on a {8:batch, 2:model} TPU mesh.

constraints baked into the model code to resolve conflicts; and GSPMD--, which does not use internal sharding constraints for conflict resolution. We evaluated this on UNet with BP and Z2/Z3 – two partitioning strategies that cause conflicts discussed in Section [5.2.3.](#page-7-1) Furthermore, we show the addition of a Megatron-like [\[54\]](#page-15-3) MP tactic to UNet along the model axis. We performed a similar experiment with the transformer benchmarks used in [7.2,](#page-8-0) and (somewhat surprisingly) obtained comparable results of GSPMD and GSPMD--, potentially because GSPMD internal heuristics to resolve conflicts have been highly tuned for this kind of workload.

PartIR achieves faster runtime compared to the baselines; (2) incrementality is fundamental for our design, PartIR-st generated programs that exceeded the device memory limit without a natural way to resolve the conflicts generated by these tactics; (3) in multi-axes settings, even when we do not expect the tactic to cause conflicts (e.g., BP+MP), the lack of incrementality can cause a performance regression in the GSPMD case; (4) in comparison, without sharding constraints, GSPMD-- produces programs that fit but are noticeably slower compared to PartIR; and finally (5) once we did manage to obtain the optimal sharding constraints for GSPMD (which involved human labor to identify these

places where annotations might be needed) the performance of the two systems was similar.

7.5 PartIR partition time evaluation

Figure 8: PartIR partitioning vs. overall compilation time.

In Figure [8,](#page-10-3) we show that PartIR partitioning time is a small percentage (max of 14%) of the overall compilation time (XLA compilation), which is important for an interactive user workflow. Furthermore, these models usually train for several days or even months; hence, even a very long partitioning time would be acceptable for our users.

8 Discussion and limitations

Padding and spatial partitioning Value tiling and propagation via loops assume that the number of devices in an axis must exactly divide a partitioned dimension; otherwise, propagation gets blocked. In addition, partitioning convolutional NNs on spatial dimensions requires communicating with neighboring devices [\[10,](#page-12-10)[21\]](#page-13-11). PartIR has limited support for these features (via slice and loops with padding, striding, and special lowering) as we have not encountered a high demand. GSPMD [\[67\]](#page-16-1) offers a more comprehensive solution.

Reshape support Reshape ops pose a challenge: Consider a reshape from tensor<16xf32> to tensor<4x4xf32>. First, assume a 1D mesh of 4 devices, {"A":4}. It is straightforward to express a tiled version of the reshape as a PartIR loop:

```
\chiy = loop "A" [tile <0>] (\chir: range <4>) {
 \chis = slice 0 \chix[\chir]: tensor <16xf32> -> tensor <4xf32>
 \chi_r = reshape \chi_s : tensor <4xf32> -> tensor <1x4xf32>
 yield %r } : tensor <4x4xf32>
```
Now, assume that the mesh axis spans over 8 devices, such that it becomes too large to return chunks of the tensor<4 x4xf32> array, and propagation will get blocked. Intuitively the solution is to logically reshape mesh {"A":8} to {"A1 ":4, "A2":2}, in which case propagation over the "A1" axis will work. Unfortunately, PartIR does not consider mesh transformations like that in the middle of propagation. By contrast, GSPMD [\[67\]](#page-16-1) can, during propagation, manipulate the mapping of logical IDs to data, as it defines the sharding directly in terms of logical device IDs, which comes at the cost of lower-level reasoning about the sharding representation.

Program rewriting versus annotations PartIR departs from the traditional view in HPC of distribution as a data layout problem. Following that approach, GSPMD [\[67\]](#page-16-1) separates the propagation of sharding annotations from code generation, which deals with inserting and optimizing collectives. By contrast, PartIR rewrites the program incrementally, which is less efficient (esp. as part of the automatic tactic), and relies on pattern matching on the IR loop structure for propagation, which is brittle. On the upside, the PartIR loops and rewriting help with correctness verification since loops reflect the semantics in the IR and allow for temporal interpretation and testing without actual partitioning.

Explicitly replicating values PartIR propagation greedily partitions the program (c.f., Section [5.2.2\)](#page-6-0), which may partition tensors the user wants to replicate. For example, by partitioning the optimizer state, propagation may also shard the parameters, which is not desired for Z2, where parameters must be replicated (Section [2.2\)](#page-2-4). For this reason, PartIR exposes an explicit atomic<value, axis> action, which creates trivial loop rewrites whose sole purpose is to block propagation and keep a value replicated. For example atomic<%, "M">) replaces x with the loop:

 χ_{XT} = loop "M" [any] ($\chi_{\text{r:range}}$ <... >) { yield χ_{X} ; }

The any attribute works as a "consensus" monoid – all devices are guaranteed by construction to compute the same value, and the loop range index cannot be used in the body.

Model-internal annotations. Although sequentialization of decisions lets us handle most conflicts, as seen in Section [7.4,](#page-9-2) we are still left with corner cases. For example, consider a component of matrix diagonalization, where a matrix is multiplied by its transpose:

```
func \mathbb{G} main \binom{y}{k} : tensor < (256x256xf32>) -> ... {
  %tx = transpose %x {dims=[1,0]} : ...
  \gamma y = \text{matmul} (\gamma x, \gamma t) ...
```
If we shard %x on dimension 0 along a given mesh axis "M", then %t (its transpose) is sharded on dimension 1. That is a propagation "conflict" and prevents the matrix multiplication sharding. To resolve this conflict, users must apply an atomic action on the intermediate tensor %tx before partitioning it, which is allowed as long as users name them, using a primitive called tag. For example:

```
func @main (\frac{9}{6}x: tensor < (256x256xf32>) {
  %tx = transpose %x {dims=[1,0]}%tag_tx = tag "transposed" %tx
```

As expected, the final partitioned multiplication requires an all_gather for its second operand:

9 Related work

The fast growth of ML models opened the floor to new partitioning tools [\[47,](#page-15-10) [53\]](#page-15-1), as frameworks like TensorFlow [\[1\]](#page-12-4) and PyTorch [\[41\]](#page-14-2) support only data and limited model parallelism. JAX [\[4\]](#page-12-5) provides two main partitioning APIs: jax. jit, which surfaces GSPMD [\[67\]](#page-16-1) (which itself builds on GShard [\[32\]](#page-14-1)); and shard_map, which disables GSPMD and lets users manually perform communication across devices. PartIR builds on top of some of JAX's partitioning infrastructure (e.g., meshes), but instead of users annotating inputs, outputs and intermediate values with sharding annotations or communication collectives in the case of shard_map, our users define their partitioning strategies using schedules, which resemble ideas found in kernel-generating schedulebased systems [\[9,](#page-12-9)[16,](#page-13-7)[29,](#page-14-10)[45,](#page-15-7)[68\]](#page-16-10). Although we took inspiration from Halide schedules [\[45\]](#page-15-7), PartIR differs in that they are applied to entire programs that span multiple devices rather than generating small program kernels for a single device.

Similar to Lift [\[56\]](#page-15-11) and RISE [\[17\]](#page-13-12), PartIR is inspired by functional-style IRs [\[57\]](#page-15-12) that transforms programs by equality-based rewriting [\[63\]](#page-16-12) and similar to the functional array representation in $[42]$. In contrast to DaCe $[3]$, which allows the user to apply graph transformer interactively by employing a representation based on data flow graphs. DistIR [\[50\]](#page-15-13) exposes a Python API with explicit device placement and point-to-point communication to program the distribution directly. PartIR:Core abstracts away distribution and deals with it during SPMD lowering.

10 Conclusion and Future Work

PartIR is an MLIR-based compiler that enables programmers and automatic tools to partition tensor programs effortlessly. Users interact with PartIR using a schedule of tactics; each tactic is translated into a series of rewrite actions to be applied by the compiler. It is implemented as a stack of IRs to express partitioning at different levels of abstraction. It includes a powerful propagation system that, because of its incremental design, partitions programs in a predictable way without relying on cost-based heuristics to handle conflicts. In the future, we want to support MPMD partitioning across multiple device meshes to support pipelining [\[22,](#page-13-13) [33,](#page-14-14) [34\]](#page-14-15) or heterogeneous device clusters, which will require new sets of sharding and optimization tactics (e.g., scheduling.)

A Experiments extended

A.1 MFU

We evaluated the MFU to compare SOTA performance in Section [7.2,](#page-8-0) here we document what is MFU. MFU is defined as a ratio of actual FLOPs per second and theoretical FLOPs per second:

> $100 \times \frac{\text{model FLOPs}/\text{step time (s)}}{\text{total FLOP}}$ #devices×peak FLOPs per second

An MFU of 100% indicates that the model is utilizing the full computational capacity of the hardware.

A.2 Hardware details

Our experiments were run on Nvidia A100 [\[37\]](#page-14-12) as the GPU baseline and TPUv3 [\[12\]](#page-12-0) for the TPU baseline. Here we outline their specs as outlined in their respective websites:

Nvidia A100 We use the A100 40GB memory HBM2 version; it performs 156 TFLOPS on float32 and 312 TFLOPS for bfloat16. The A100s are connected using Nvidia's NVLInk, which can do 600GB/s data transfer.

TPUv3 For the TPU experiments, we use the TPUv3 chips; each chip comes with two tensor cores. Each tensor core has 16GiB HBM2 memory capacity, each capable of 61.5 TFLOPs on float32 and 123 TFLOPs on float16. The chips are connected over four links, each capable of doing 70GB/s data transfer [\[25\]](#page-13-14).

A.3 Benchmark details

The details of the benchmarks used are as follows:

- U-Net A model variant used in the reverse process of a diffusion model [\[19\]](#page-13-8). It uses 9 residual blocks for the down-sampling convolutions and 12 for up-sampling, and between them, there are two residual blocks and one attention layer. The attention layer has 16 heads and a resolution of $16\times8\times4$. Pairs of convolutions have a hidden channel size 4 times larger than the input/output channel size. This allows for efficient partitioning along the channel dimensions.
- GNS A Graph Network Simulator [\[49\]](#page-15-8) model used in molecular property prediction [\[14\]](#page-13-9), configured with 5 MLP layers of hidden size 1024. The network is configured with 24 message-passing steps and a latent size of 512. We set the number of nodes to 2048 and vary the number of edges between 8192 and 65536 in powers of 2.
- T32) A 32 layers Transformer model based on Chinchilla [\[20\]](#page-13-2), with additional normalization layer. We configure with input batch size 48, 32 heads and $d_{model} = 4096$, with the standard 32k vocabulary size for the embedding.
- **T48)** A scaled-up variant of T32, scaled to 48 layers, and configured with input batch size 64, 64 heads and $d_{model} = 8192$, with the standard 32k vocabulary size for the embedding.

All models were trained using the Adam optimizer [\[28\]](#page-14-16). We turned off XLA rematerialization in all runs.

A.4 Composing automatic and manual tactic

Table [3](#page-18-0) provides the the full metrics of using AutomaticPartition to find sharding strategies.

A.5 Simulation results

Here, we show how close our simulator can approximate real performance on the TPUv3 32 device described in Section [7.3.1.](#page-9-1) While the details of the simulator we leave to another paper, it is indeed a very simple simulator due to most of the heavy lifting done by our PartIR:HLO dialect. PartIR:HLO generates device-local communication ops that reference the mesh and device, and PartIR keeps a registry of popular compilation devices (and it is easy to extend, requiring only high-level device specs). Combining both the PartIR:HLO code, which has tensor shapes, and communication ops on each device, with the target specs, our simulator iterates over each SPMD context, tracks the live memory, and counts flops usage for the communication

Table 3: Collective and simulator cost estimation of various tactics

ops also tracks the byte transfers. Using the target device specs, it would estimate its statistics. This simple analytical cost model worked well for our AutomaticPartition tactic and user debugging. While the absolute values are not guaranteed to be correct, the relative improvements should still be sound. For example, applying a BP tactic, you would expect the memory and flops usage to be reduced by a factor of the number of devices in the mesh if the BP was applied correctly. A search algorithm that will seek to improve the relative partitioning of the model will also benefit from this simple analytical function.

Hardware measurement follows the methodology described in Section [7.1.](#page-8-4) All experiments were run on a 32 TPUv3 as described in the evaluation section Section [7.3.1.](#page-9-1)

A.5.1 Runtime estimation

First, we look at the difference between the estimated and actual runtime for the various strategies described in the paper. Figure [9](#page-19-0) shows the difference between the estimated and actual measured seconds on hardware. First, we notice that the error is within acceptable range (sub milliseconds) for specific configurations, especially for GNS and UNET. The simulator underestimated T32's most complicated strategy by 3 seconds at the worst case; these often can be attributed to the layout pass of XLA and XLA optimization. IT32, on the other hand, the simulator overestimated its runtime (meaning we thought it would be slower than it is); this is due to the key-value caching optimization we implemented in the model; without caching, the numbers are much closer to the T32 error range. Overall, both automatic tools and human users use the estimated runtime as a proxy for relative improvement of applying the sharding strategy rather than absolute value estimates.

Absolute value estimates require a learned cost model that learns what the backend compiler optimizer will do, different network topology profiles, and various specialized ops performances (e.g., caching). Improving the simulator is beyond the scope of our work, but PartIR allows the end to plug in any simulator, and we are currently looking into a learned cost model for this exact reason.

A.5.2 Memory estimation

Related to runtime estimation is memory estimation; this is more important for automatic tools to learn if any proposed solution does not fit in the given device specification. We implement a live range analysis of a tensor usage in a given SPMD

Figure 9: PartIR's simulator runtime estimation compared to the actual measured runtime, in seconds, closer to the zero better.

context at the PartIR:HLO level, where we follow a tensor as long as it is being used; we also implement a simple fusion heuristic that will predict what the backend compiler will do to the tensor. The results are shown in Figure [10.](#page-20-0) Here, we can see the results are much closer to 0 (i.e., no error); often, we prefer to over-estimate the memory usage to discourage solutions close to the boundaries. XLA and other backend compilers have specialized optimization when a model is on the boundaries - such as remating parts of the computation or reducing the fusion of ops. The simulator forces the automatic partitioners to avoid these regions and focus on models that fit comfortably, not to kick off aggressive memory optimization from the backend compiler.

A.5.3 Partitioning time

We showed the partitioning time of manual partitioning tactics in Section [7.5;](#page-10-0) here, we show the time it takes to run AutomaticPartition. AutomaticPartition tactic depends on the algorithm implementation used for the search; we implemented an algorithm similar to the one described in [\[2,](#page-12-6) [51\]](#page-15-2). As PartIR is agnostic to the optimization algorithm, we are looking at different algorithms to implement, such as ILP solvers or RL-based solutions. Different algorithms have different search profiles, and naturally, by increasing the number of axes (and, as a result, the number of available decisions to make), PartIR automatic partitioning time does increase, as can be seen in Figure [11.](#page-20-1) Even in the worst-case scenario, we see a search time of 1250 seconds, which might be a lot compared to the manual tactic (hence we allow composing manual and automatic tactics and benefit from both). However, we want to argue that: 1) the search time reduces the cognitive workload on the ML practitioner and saves them time from writing their sharding strategies and testing them; 2) these models train for weeks on end, a search time of 20 minutes is within the amortized acceptable range, especially when the shardings found can outperform known strategies; 3) we are actively developing the search mechanism and exploring different techniques, we expect this to only get faster with time.

A.6 Schedules

Here, we provide the tactics we used for all the experiments; we note that the schedule is simply a list of these tactics as they appear in the order. For example, to replicate the schedule $BP+MP$, define the tactic as bellow, then pass to partir.jit(fun, schedule=[bp, mp]).

Figure 10: PartIR's simulator estimates of memory compared to the actual measured memory, in GB, closer to the zero better.

Figure 11: PartIR's automatic partitioning tactic search time compared to manual partitioning.

Batch parallelism and zero Regardless of the module, both tactics can easily be expressed as:

• BP: shard the 0th dimension of the inputs, assuming the NN's update function takes X where its 0th dimension is the batch dimension:

```
BP = ManualPartition (inputs = { "X" : 0}, axis = "batch")
```
• Z3: shard the 0th dimension of the gradients, and optimizer state, but replicate the parameters:

```
Z2 = ManualPartition (inputs={'params': partir . REPLICATED, 'opt_state': partir . FIRST_DIVISIBLE_DIM}, axis ="
    batch ")
```
- Z3: shard the 0th dimension of the parameters, gradients, and optimizer state,
- Z3 = ManualPartition (inputs={'params': partir.FIRST_DIVISIBLE_DIM, 'opt_state': partir . FIRST_DIVISIBLE_DIM}, axis =" batch ")

Our tactics take a callback that applies a sharding based on the parameter name in the NN, this is useful for Megatron and model parallelism tactics.

T32/T48/IT32 tactics There is no difference in tactics applied to any of the transformer models, showing the usefulness of separating the model code from the sharding strategies.

MP: here we apply the Megatron [\[54\]](#page-15-3) sharding strategy.

```
def model sharding ( param name ) :
  if not 'w': # only shard the weights
    return UNKNOWN # Let the infer-propagate decides.
  if multi_head_attention_regex . contains ( param_name ):
  return 0 # shard the linear weights on 0th dimension
if 'dense_up ' in param_name :
    # dense layer on its cols
    return 2
  if 'qkv_einsum ' in param_name :
     # the queries on first dimension
     return 1
```
MP = ManualPartition (inputs ={ 'params ': apply (_model_sharding)} , axis =" model ")

UNet tactics

• MP: here we try to mimic the Megatron sharding strategy.

```
def _model_sharding ( param_name ):
        if not 'w': # only shard the weights
return UNKNOWN # Let the infer-propagate decides.
        if multi_head_attention_regex . contains ( param_name ):
        return 0 # shard the linear weights on 0th dimension
if ' conv_residual_block ' in param_name :
          # shard the convolutions on their weights not stride.
          return 3 if is_2d_conv ( param_name ) else 2.
MP = ManualPartition ( inputs ={ 'params ': apply ( _model_sharding )} , axis =" model ")
```
GNS tactics

• ES: Simply performs search on the batch axis.

```
# Shard both the sender and receivers of GNS that is using jraph library.
# predictions is a custom name inside the GNS implementation.
ES = ManualPartition (inputs={'edges': {''predictions": 0, "predictions_targets": 0}}, axis="batch")
```
Automatic tactics These tactics are the simplest.

- AutoBP: Simply performs search on the batch axis. AutoBP = AutomaticPartition (axes = ["batch"])
- AutoMP: Simply performs search on the model axis. AutoMP = AutomaticPartition (axes = ["model"])
- AutoAll: Perform search on all axes: AutoAll = AutomaticPartition (axes=["batch", "model"])

B PartIR:Core extended

Here we discuss extended details around PartIR:Core omitted from Section [5.](#page-5-0) This section mostly focuses on the multi-axis case, how does the propagation and loop construct handle nesting for multiple axes (a 2D or higher dimensions mesh).

B.1 Multi-axis propagation and deep-tiling

B.1.1 Multi-axis analysis for propagation

Propagation becomes involved in the presence of multiple axes. Checking whether some operand is overly tiled or a result is overly sliced requires a deeper look into the definitions of operands or uses of results. For example, consider the following:

```
\chi = loop "a" [#sum] (\chira: range <4>) {
   %t = loop "b" [#tile < 0] (%rb: range < 2) { ... }yield %t
}
\chiz = matmul (\chix, \chiy)
```
To realize that the left matmul operand is tiled, we have to look internally under the reduction loop. The situation is even more complex when both tiling loops and slices are involved:

```
\%x = loop "a" [#tile <0>] (\%xa: range <4>) {
  %t = loop "b" [#tile <0>0] (%rb: range <2>) { ... }yield %t
}
\%w = loop "a" [#tile <0>] (\%ra: range <4>) {
    %sx = slice 0 %x [%ra]
    \chiz = matmul (\chisx, \chiy)
    ...
}
```
In this situation the left matmul operand is not even the result of a loop op, it is just a slice! However, if we keep looking backwards, we discover that the argument %x of the slice instruction is produced by a tiling loop over "a" that can cancel out the slice, and internally there is yet another tiling loop, i.e. over "b". Consequently, we could rewrite the matmul as a loop over "b".

What the examples highlight is that when multiple axes are involved, it is necessary to traverse nests of loop operations as well as chains of slice operations to avoid missing relevant matches. A dual situation applies to slice operations in backward propagation, where we need to apply a forward analysis starting at the uses of the result of an operation. To deduce whether there is a match on the TMR entry one would have to look *inside* the loop over axis "a" to determine that dimension 0 is indeed tiled across axis "b". A dual situation arises with overly sliced results, where one may need to look inside chains of slice operations. For this reason PartIR employs a simple static analysis to determine the per-dimension excess tiling (or slicing) for the operands (or results) of an operation.

B.1.2 Deep tiling

A big design goal of PartIR is to support incremental partitioning (sometimes called "recursive partitioning" [\[67\]](#page-16-1)) that never undoes previous actions. Consider a value %x that is already sliced (e.g. due to previous value tiling or propagation) along axis "a":

```
%xt = loop "a" [#tile <1>] ({\%}ra: range <4>) {
  x s = slice 1 x x [x ra]);
  ...
}
```
Imagine a user or a tool needing to further tile the value %x across axis "b" and dimension 1. It would be wrong to perform a flat value tiling – instead we need to gather up any existing sliced uses of %x and apply what we call a "deep" tiling action. In code:

```
// WRONG: would undo previous actions
// %xtt = loop "b" [#tile<1>] (%rb: range<2>) { yield (%slice 1 %x[%rb]) }
// CORRECT: deep tiling over both previous and new axes!
%<mark>xtt</mark> = loop "a" [#tile <1>] (%ra: range <4>) {<br> %t = loop "b" [#tile <1>] (%rb: range <2>) {
     %xsa = slice 1 %x[%ra]%xsb = slice 1 %xsa[%rb]yield %xsb
  }
```

```
yield %t
}
 %xt = loop "a" [#tile<1>] (%ra: range<4>) {<br>%tmp = slice 1 %<mark>xtt</mark>[%ra];
 ...
}
```
Using the multi-axis analysis from Appendix [B.1.1,](#page-22-1) PartIR is able to deduce the full tiling context that needs to be inserted during value tiling, including previous slicing uses and the new tiling requested. This applies to both user-initiated value tilings as well as inference-initiated value tilings.
