AWS AI Labs, Amazon

Abstract

Large language models (LLMs) have shown incredible proficiency in performing tasks that require semantic understanding of natural language instructions. Recently, many works have further expanded this capability to perceive multimodal audio and text inputs, but their capabilities are often limited to specific fine-tuned tasks such as automatic speech recognition and translation. We therefore develop SpeechVerse, a robust multi-task training and curriculum learning framework that combines pretrained speech and text foundation models via a small set of learnable parameters, while keeping the pre-trained models frozen during training. The models are instruction finetuned using continuous latent representations extracted from the speech foundation model to achieve optimal zero-shot performance on a diverse range of speech processing tasks using natural language instructions. We perform extensive benchmarking that includes comparing our model performance against traditional baselines across several datasets and tasks. Furthermore, we evaluate the model's capability for generalized instruction following by testing on out-ofdomain datasets, novel prompts, and unseen tasks. Our empirical experiments reveal that our multi-task SpeechVerse model is even superior to conventional task-specific baselines on 9 out of the 11 tasks.

1 Introduction

Large language models (LLMs) [1–3] have achieved remarkable performance on a variety of natural language tasks through self-supervised pre-training on massive text corpora. They have also shown a striking ability to follow open-ended instructions from users through further instruction tuning [4–7], enabling strong generalization capabilities. Despite the success, a significant limitation lies in the inability of language models to perceive non-textual modalities such as images and audio.

Speech in particular represents the most natural mode of human communication. Empowering LLMs to deeply understand speech could significantly enhance human-computer interaction [8] and multimodal dialog agents [9, 10]. As such, enabling LLMs to comprehend speech has received

^{*}Equal Contributions

Figure 1: Schematic diagram of the SpeechVerse framework.

substantial attention recently. Some approaches first transcribe speech via an automated speech recognition (ASR) system and then process the text with an LLM for improved transcription [11–13]. However, such pipelines cannot capture non-textual paralinguistic and prosodic features like speaker tone, intonation, emotion, valence, etc.

A promising new paradigm directly fuses textual LLMs with speech encoders within an end-toend training framework [14, 15]. Enabling joint modeling of speech and text holds promise for richer speech and audio comprehension versus text-only methods. Particularly, instruction-following multimodal audio-language models [16–18] are increasingly receiving more attention due to their generalization capability. Despite some success, existing works in multi-task audio-language models such as SpeechT5 [19], Whisper [20], VIOLA [15], SpeechGPT [18], and SLM [17] are limited to processing a small number of speech tasks.

We therefore propose SpeechVerse, a robust multi-task framework that leverages supervised instruction finetuning to incorporate various speech tasks (see Figure 1). In contrast to SpeechGPT [18], we propose using continuous representations extracted from a self-supervised pre-trained speech foundation model, focusing on tasks that generate text-only output. More recently, [16] proposed Qwen-Audio, a multi-task audio-language model capable of perceiving human speech and sound signals and is trained on 30 tasks from diverse audio types including music and songs. However, this requires carefully designed hierarchical tagging and a large-scale supervised audio encoder for fusion making it sub-optimal for unseen speech tasks. In contrast, our training paradigm incorporates multi-task learning and supervised instruction finetuning in a unified curriculum, without the need for task-specific tagging, allowing for generalization to unseen tasks using natural language instructions.

We summarize our contributions below:

- 1. Scalable multimodal instruction finetuning for diverse speech tasks. SpeechVerse is a novel LLM-based audio-language framework to scalably exhibit strong performance on as many as 11 diverse tasks. We extensively benchmark our models on public datasets spanning ASR, spoken language understanding and paralinguistic speech tasks.
- 2. Versatile instruction following capability for novel open-ended tasks. We demonstrate the SpeechVerse model's capability to leverage the robust language understanding of the LLM backbone in order to adapt to open-ended tasks that were unseen during multimodal finetuning.
- 3. Strategies for improving generalization to unseen tasks. We further study prompting and decoding strategies including constrained and joint decoding, that can enhance the model's ability to generalize to completely unseen tasks, improving absolute metrics by up to 21%.

2 Approach

2.1 Architecture

As shown in Figure 2, our multimodal model architecture consists of three main components: (1) a pre-trained audio encoder to encode an audio signal into a feature sequence, (2) a 1-D convolution module that operates over the audio feature sequence to abbreviate the sequence length, and (3) a pre-trained LLM to use these audio features and textual instructions to perform the required task. Details of each of these sub-systems are described below.

Audio encoder: To extract semantic features from a given audio, we use a large pre-trained selfsupervised speech foundation model as an audio encoder. We can represent the audio encoder as a cascading collection of *L* layers, where each intermediate layer *l* returns a feature sequence $\mathbf{h}^{(l)} = f_{AE}(\mathbf{h}^{(l-1)}; \theta_{AE}^{(l)})$, where $\mathbf{h}^{(0)} = \mathbf{x}$ is the input audio. Here, $\theta_{AE}^{(l)}$ represents the learned weights for layer *l* of the pre-trained speech model. To capture a unified representation for multifaceted forms of feature semantics, we compute the output of the audio encoder as:

$$AE(\mathbf{x}) = \frac{1}{L} \sum_{l=1}^{L} w^{(l)} \mathbf{h}^{(l)}$$
(1)

where, the scalars $\{w^{(1)}, \dots, w^{(L)}\}\$ are a set of learnable parameters. As this approach concurrently encodes features from multiple intermediate layers of the speech foundation model, it can simultaneously capture different forms of semantics (higher-order as well as lower-order features), leading to better generalization across a diverse set of tasks. We also perform experiments by only taking the output from the last layer of the audio encoder, i.e., $AE(\mathbf{x}) = \mathbf{h}^{(L)}$.

Convolution downsampling module: LLMs trained on text-only input encode token sequences which are typically of a considerably shorter length compared to the feature sequences encoded by speech foundation models. To mitigate this large discrepancy in length distribution between audio features and text tokens, we downsample the encoded audio features through a learnable convolution module. This module consists of successive blocks, each having a 1-D convolution layer followed by layer normalization. For the 1-D convolution, we use a kernel size of 3, which ensures that each output frame has both left and right context from the input frames. In our experiments, we use as many number of these downsampling blocks as necessary such that the resulting sampling rate for the audio comes out to be 12.5 Hz, i.e., each output frame corresponds to 80ms of audio. By fine-tuning the convolution downsampling module, the audio encoder output can be transformed from an audio-only feature space to a joint audio-text semantic space. Hence, we set the number of output channels for the 1-D convolution to be equal to the feature dimension of the token embeddings for the downstream LLM. We can represent the output of the convolution downsampling module as $CNN(\mathbf{x}) = f_{CNN}(AE(\mathbf{x}); \theta_{CNN})$, where θ_{CNN} represents learnable parameters of the 1-D convolution blocks.

Large Language Model: An LLM typically takes in a sequence of input text tokens z and models the probability of observing an output text sequence y as the possible next tokens for the input text. The text tokens are converted to vectorized embeddings EMB(z) using a lookup matrix that is learned during training. The output of the LLM can be represented as $LLM(z) = f_{LLM}(EMB(z); \theta_{LLM})$, where θ_{LLM} are the weights of the LLM. In this work, we leverage a pre-trained LLM for multimodal tasks. For formulating the multimodal input with audio x and text sequence z, we simply concatenate the downsampled audio features (CNN(x)) with the token embeddings ((EMB(z))) in the sequence dimension as shown in Figure 2. Hence, we can represent the probability distribution over the output from our multi-modal Spoken Language Model (SLM) as:

$$SLM(\mathbf{x}, \mathbf{z}) = f_{LLM} \left(\left[CNN(\mathbf{x}), EMB(\mathbf{z}) \right]; \theta_{LLM} \right)$$
(2)

2.2 Multimodal Instruction Finetuning

Let $\mathcal{D}^{\tau} = {\mathbf{x}^{\tau}, \mathbf{y}^{\tau}}_{1}^{n^{\tau}}$ represent a labelled dataset for a task τ with n^{τ} samples where each sample consists of audio sequence \mathbf{x}^{τ} and a corresponding text label sequence \mathbf{y}^{τ} . Let $\mathcal{P}^{\tau} = {\mathbf{p}^{\tau}}_{1}^{m^{\tau}}$ be a set of m^{τ} textual prompts/instructions sequences \mathbf{p}^{τ} describing the task. In our experiments, we do a weighted combination of datasets from each of the M training tasks ${w^{\tau}, \mathcal{D}^{\tau}}_{1}^{M}$ where w^{τ} is the weight given to each sample of task τ . This is done to ensure balance between tasks with different complexities and training data sizes. Thus, each sample can be represented as a tuple $(\mathbf{x}^{\tau}, \mathbf{p}^{\tau}, \mathbf{y}^{\tau})$ where \mathbf{x}^{τ} is the audio sample, \mathbf{p}^{τ} is a prompt/instruction sampled uniformly from \mathcal{P}^{τ} and \mathbf{y}^{τ} is the label. Then the probability for predicting the labels \mathbf{y}^{τ} can be defined as:

$$p(\mathbf{y}^{\tau}|\mathbf{x}^{\tau},\mathbf{p}^{\tau};\Theta) = SLM(\mathbf{x}^{\tau},\mathbf{p}^{\tau})$$
(3)

where $\Theta = \{\theta_{AE}, \theta_{CNN}, \theta_{LLM}\}$ are all the parameters of our audio language model. The selfattention layers in the LLM attend to both the audio and the textual instruction to generate the required output on any audio-related task. We use the standard gradient descent method to maximise the likelihood of producing the target label \mathbf{y}^{τ} for each sample in the training dataset as defined below:

$$\mathcal{L}(\Theta) = -\log p_{(\mathbf{x}^{\tau}, \mathbf{p}^{\tau}, \mathbf{y}^{\tau}) \sim \{\mathcal{D}^{\tau}\}_{1}^{M}}(\mathbf{y}^{\tau} | \mathbf{x}^{\tau}, \mathbf{p}^{\tau}; \Theta)$$
(4)

2.3 Curriculum Learning with Parameter Efficient Finetuning

To ensure faster convergence and avoid catastrophic forgetting and overfitting by the pre-trained LLM, we adopt a parameter efficient approach based on low-rank adaptation [21], or LoRA, for training our multimodal models. In this work, we freeze the pre-trained audio encoder and LLM, and only train the convolution downsampling module and the LoRA adapter. Since the bulk of the parameters (θ_{AE} and θ_{LLM}) are never updated throughout the training process, it makes our framework compute efficient and allows us to scale to a large number of diverse datasets and tasks with limited compute resources. Moreover, it enables leveraging the existing capabilities of both pre-trained audio and language models without catastrophic forgetting. However, when training both the downsampling module and the LoRA adapter from scratch on a diverse set of speech tasks, we observe frequent gradient explosion, leading to suboptimal convergence. Hence, we carefully design a curriculum of two stages for training.

In the first stage, we only train the convolution downsampling module and the intermediate layer weights without introducing the LoRA adapters. Further, only the samples from the automatic speech recognition (ASR) task are used in this stage. Since the encoded speech feature vectors can be very different from the token embeddings of the text input, this stage can help align them more easily in a common embedding space by only learning the parameters for the convolution downsampling module in the confined task space of ASR. This enables a pre-trained text-based LLM to attend to the content of the audio sequence and generate the speech transcription.

In the second stage, we now introduce the LoRA adapters for training the model. In this stage, the intermediate layer weights, the downsampling module as well as the LoRA adapters are unfrozen. Since the LoRA adapters are training from scratch, we first allow the adapter weights to warmup by training only on the ASR task, so as to get aligned to the common embedding space learned by the convolution downsampling module in the first stage. Finally, we introduce additional tasks on top of the ASR task and continue training while keeping the pre-trained audio encoder and LLM weights frozen. Since the warmup using only the ASR task enables the model to understand the contents of

the audio, our curriculum learning approach leads to faster convergence on a variety of speech-based tasks that rely on the spoken contents of the audio.

3 Experiments

3.1 Tasks

In this work, we use a large collection of publicly available speech datasets from a diverse set of tasks. A summary of the datasets and evaluation metrics for these tasks is provided in the Table 1, while examples and prompts are covered in the Table 10. Our training tasks include automatic speech recognition (ASR), five spoken language understanding (SLU) tasks, and five paralinguistic speech processing (PSP) tasks. The SLU tasks include those tasks which can be solved by a cascaded system of a ASR model and an LLM, while PSP tasks are classification tasks based on the audio, typically used in audio analytics. For the IC/SL tasks, we split the SLURP dataset into seen and unseen intent/slot label classes and study them separately to understand the generalization capabilities of the model. The KWE task is about finding important keywords from the audio, while in the KWS task, we learn to classify whether a particular keyword was present in the audio or not. The target labels were synthetically created for both these tasks using an LLM. All other tasks are standard and an interested reader can refer to the Appendix A.3 for more details. We create a list of at least 15 prompts per task describing the goal of the task. To further add diversity to the set of tasks, we use a text-to-speech (TTS) version of the Alpaca dataset [31]. This dataset contains a diverse collection of prompt, input, output tuples, where the prompt describes the task, input is the input for the task, and the output contains the target labels. However, there are no corresponding audios associated with the dataset. As in the existing work [17], we use a TTS system (AWS Polly in our case) to generate synthetic audios for the input text using a pool of 10 different speakers.

3.2 Models

We train three different variants of multimodal models using our SpeechVerse framework, namely, (1) **Task-FT**: These represent a set of models where each model is trained individually for a particular task τ . While most tasks have separate model, datasets from certain related tasks like IC/SF, KWE/KWS, and ER/ASC are trained together. (2) **Multitask-WLM**: This represents a single multi-task model trained by pooling datasets for all the tasks together. Both (1) and (2) uses a pretrained WavLM Large [32] as the backbone audio encoder and only uses the last encoder layer output $AE(\mathbf{x}) = \mathbf{h}^{(L)}$ as the

representation of the audio. (3) **Multitask-BRQ**: This model is similar to (2), but it uses the Best-RQ [33] architecture for the audio encoder. Because the Best-RQ encoder is trained using a random projection quantizer, the middle layer weights are more suited for downstream tasks if the encoder is frozen during fine-tuning. We therefore used a unified representation that combines representations from all layers via learnable weights for the multitask model trained with the BEST-RQ encoder. The details about the pretraining of this audio encoder are described in the Appendix A.1. All the three variants of our models are trained using curriculum learning as highlighted in the Section 2.3. All the models use Flan-T5-XL [5] as the backbone LLM. The LoRA adapters introduced in Task-FT models have rank (r) = 8, while multitask models use r = 16, allowing more learnable parameters for solving a diverse collection of tasks. The complete list of hyper-parameters and training setting is provided in the Appendix A.2.

Baselines: For the SLU tasks, we compare our models with a cascaded baseline that uses an LLM on ASR hypotheses (ASR \rightarrow LLM). For a fair comparison, we use a parameter-efficient fine-tuned version of Flan-T5-XL as the LLM for the baseline. The multi-task fine-tuning data is exactly the same between our models and the baseline except that the latter uses ground truth text in place of the audios. We benchmark the cascaded approach with ASR hypotheses from (1) a strong publicly available Whisper-large-v2 [20] ASR model and (2) our ASR Task-FT SpeechVerse model, enabling a true comparison between a multimodal model vs cascaded approach. Finally, we also benchmark the performance of the oracle ASR system by passing the ground truth transcripts to the baseline LLM (GT \rightarrow LLM). For the KWS task, we use substring search of the keyword in ASR hypotheses as the baseline. For PSP tasks, we train task-specific classifiers that use the last layer representations from WavLM Large. The classifier contains a feed-forward layer, followed by a 2-layer Gated Recurrent Unit (GRU) with mean pooling over frames, followed by another 2 layers of feed-forward network and finally a softmax operator. These models are trained on the same task-specific data thereby allowing for direct comparison with our WavLM-based multimodal models.

4 Results

4.1 Evaluation of SpeechVerse models

We evaluate end-to-end trained joint speech and language models (E2E-SLM) leveraging the Speech-Verse framework on 11 unique tasks across multiple domains and datasets. We first evaluate Speech-Verse's core speech understanding capability through ASR benchmarks. We then evaluate more complex SLU tasks and paralinguistic speech tasks in Tables 2 and 3 respectively.

4.1.1 Performance on ASR and SLU tasks

First, we evaluate the performance of SpeechVerse models on four public ASR benchmark datasets namely *libri-test-clean*, *libri-test-other*, *Voxpopuli* and *CommonVoice*. The WER numbers for each of these datasets are reported in Table 2. SpeechVerse ASR in row 2 uses same model as task-specific pretrained ASR model (*Task-FT*) in row 3. When comparing our task-specific pretrained ASR model, which also serves as the initialization for multi-task finetuning, to Whisper ASR, our model achieves slightly better performance on average. However, the WER increases in both multitask models with *Multitask-WLM* performing similarly to Whisper across three out of the four test sets. The lower performance of the multi-task SpeechVerse model compared to the task-specialized model is likely due to giving lower weight to ASR datasets when constructing batches during multi-task training. This was done to balance the performance across all tasks, since the data distribution is imbalanced between the different tasks.

When it comes to SLU tasks, a frequent question posed is if an end-to-end model can outperform a cascaded pipeline that transcribes speech via ASR and then feeds it to a language model. To investigate this, we conducted experiments on five semantic understanding tasks using the same foundation models as SpeechVerse. The text foundation model was further fine-tuned on data from the five SLU tasks separately, as we found the zero-shot performance of Flan-T5 on these benchmark test sets to be quite poor. We also report performance when feeding ground-truth transcripts into the fine-tuned LLM, to provide upper bound results. On 4 of the 5 tasks, excluding Keyword Extraction, the end-to-end trained models outperform the cascaded pipeline. In particular, the more commonly used tasks like intent classification, slot labeling, and speech translation are performing better than the cascaded system, demonstrating the efficacy of our models trained using SpeechVerse. We also observed that SpeechVerse models on KWS task are outperforming cascaded pipeline by an absolute 10% in accuracy, while performing significantly behind on KWE task. Since the keyword search task requires an attention span focused on a specific word of interest, joint modeling helps improve accuracy by overcoming error propagation present in a cascaded pipeline. We also conducted an ablation study to determine if the KWE task benefits further from joint decoding of ASR transcription and keywords. We noticed an improvement in performance, closing the gap to the cascaded pipeline. The results from this study are detailed further in the sub-section 4.3.2. When comparing the multitask models to the task-specific SpeechVerse models, there is a minor degradation in performance. but the difference is not substantial. Overall, the multitask model trained with either WavLM encoder or Best-RQ encoder outperformed cascaded systems in majority tasks.

4.1.2 Performance on paralinguistic tasks

The results in Table 3 demonstrate clear improvements in performance on various paralinguistic speech processing tasks when using multi-task learning compared to fine-tuning the WavLM model independently for each task. Specifically, the SpeechVerse model trained with multitask learning using Best-RQ audio encoder (Multitask-BRQ) achieves gains over the baseline WavLM model of 4.8% absolute on emotion recognition, 6.6% on audio sentiment classification, and 2.5% on accent classification. More modest gains are seen with the SpeechVerse model trained using multitask learning with WavLM encoder (Multitask-WLM). The unified representation's adaptive combination of all encoder layers helps multitask BEST-RQ model improve diverse paralinguistic task performance. Overall, multi-task learning provides noticeable improvements in model generalization and effectiveness across a diverse set of speech tasks compared to task-specific fine-tuning of the baseline WavLM model. The results highlight the advantages of learning shared representations across related tasks using multi-task learning techniques.

4.1.3 Comparison against SOTA models

Table 4 benchmarks SpeechVerse models against state-of-the-art (SOTA) models on five diverse tasks: automatic speech recognition (ASR), speech translation (ST), intent classification (IC), slot filling (SF), and emotion recognition (ER). Across these tasks, SpeechVerse demonstrates competitive or superior performance compared to prior specialized models. When comparing our task-specific pretrained ASR model, which also serves as the initialization for multi-task finetuning, to Whisper ASR, our model achieves slightly better performance on average. However, the multitask model (*Multitask-WLM*) performed similarly to Whisper across three out of the four test sets. When evaluating on speech translation across three language pairs, the task-specialized SpeechVerse model

Table 4: Comparison of SpeechVerse models to prior specialized SOTA models on five diverse tasks: automatic speech recognition (ASR), speech translation (ST), intent classification (IC), slot filling (SF), and emotion recognition (ER).

* SpeechVerse Task-FT model was re-trained for SLURP by including all intents and slots for comparison with other models.

surpassed SeamlessM4T on two pairs, while the multi-task SpeechVerse model achieved competitive performance compared to prior work on average. Both models did not perform well on English to Romanian pair. The overall performance of the SpeechVerse models on speech translation is heavily limited by the capabilities of the underlying language model FlanT5. The speech translation capabilities cannot exceed the translation quality provided by FlanT5 as the base language model. To evaluate SpeechVerse on spoken language understanding tasks like intent classification (IC) and slot filling (SF), we retrained the task-specialized SpeechVerse model by incorporating all 69 intents (both seen and unseen) as well as all slots. This allowed us to compare SpeechVerse to prior work on the complete intent and slot sets. Our SpeechVerse model achieved competitive performance to the previous SOTA (*PF-hbt-large*) on slot filling, but was significantly behind on intent classification with 5% lower absolute accuracy. However, SpeechVerse outperformed the same SOTA model (Frozen-hbt-large) by 10% when the encoder weights were frozen during fine-tuning. To further analyze the gap to prior state-of-the-art, we conducted an experiment allowing the audio encoder weights to be tunable during fine-tuning. This achieved 89.5% accuracy, matching the prior SOTA. This suggests the intent classification performance can overfit to the specific acoustic conditions of the SLURP dataset when full fine-tuning is performed. The SpeechVerse model that was trained end-to-end specifically for the task of emotion recognition achieved an 8% absolute improvement in unweighted average recall over the previous state-of-the-art model (w2v2-L-robust). In contrast, the multitask SpeechVerse model performed 3% better than the prior state-of-the-art. However, one key difference is that the previous SOTA work trained on the MSP-Podcast 1.7 dataset, while we used version 1.11 for training. The test set version remained the same between the two approaches. Overall, the SpeechVerse model demonstrated competitive performance compared to prior specialized models in some cases when evaluated across the various tasks.

Table 5: Generalization to unseen prompts: The performance of each task is assessed on three different prompts, out of which, two are unseen during training.

4.2 Generalization Across Instructions

We comprehensively study our Multitask-WLM model's ability to generalize to diverse forms of unseen instructions. As a first, we try to accomplish seen tasks with differently worded instructions than those used for training. We create novel prompts for some of the training tasks and evaluate the robustness of the model to variations in the prompt. Next, we demonstrate the model's potential to leverage the robust language understanding of the underlying LLM to generalize to completely new tasks that the model has not seen at all during multimodal finetuning.

4.2.1 Measuring robustness to prompt variations

To evaluate the effect of different prompts on the training task performance, we tested our MultiTask-WLM model with additional prompts for 3 different tasks: ASR, ST and AC. We test with three prompts per task, where one is directly taken from the set of prompts used during training, while two additional novel prompts are created by using a different wording and context. As showcased in the Table 5, the model showecased similar performance across prompts for each task. For the ASR task, we only see a minor variation of 0.3 in WER between seen and unseen prompts. Similarly for the ST and the AC task, the metric values deviates very little with the change in prompt. These small differences indicate that our model has generalized its core capabilities well and is not strongly dependent on the specific wording or context of the prompts. While prompt engineering remains important for optimal performance, these results suggest that the model has learned robust task-specific skills that transfer across the choice of prompts, at least for the tasks seen during training. For the tasks beyond those seen during training, we study the prompt design separately in a later subsection 4.3.1.

4.2.2 Open-ended Instruction Following

To study the model's ability to understand open-ended text-based as well as speech-based instructions, we prompted the model with several unrestricted creative requests that were not a part of our training curriculum. We enumerate several such examples in the Table 6. In many of these examples, the model is required to exhibit profound comprehension of both the spoken and written directives to successfully execute the task. For example, in the Creative QA task, the model has to understand the spoken request as well as the instruction prompt in order to generate a related response. In the Summarization task, the model has to correctly surmise the spoken content to generate a summary. In the Contextual Biasing task, we observe that the model is even able to correct its own output when provided with hints. The robust responses of the multi-task model with such a distributional shift in the input from the training data demonstrates the adaptability of its core instruction following skills. Rather than overfitting to the training domain, the multi-task learning approach enables the model to learn more versatile capabilities in instruction comprehension and execution that better transfer to new contexts. We provide some quantitative results on unseen tasks and labels in the next section.

	Yes	70.2	75.9	77.47	48.45	62.0

Table 7: Results on three unseen tasks with and without constrained decoding (CD). We compare the settings wherein the instruction prompt only contained the class labels v/s when descriptions were provided for each class label in the prompt.

* This is a subset of SLURP labels not seen during training

4.3 Strategies for Improving Performance

We further evaluate strategies to improve the multi-task model's performance specially for unseen tasks and class labels. First, we leverage contrained decoding [40] for tasks that have a pre-defined set of finite outcomes. Next, we also study joint decoding of the output of the task with the ASR hypotheses of the audio for certain complex spoken language understanding tasks.

4.3.1 Constrained Decoding

The work in [40] introduced a model-agnostic technique to enforce domain-specific knowledge and constraints during text generation. Building on this prior approach, we have explored applying decoding constraints to the SpeechVerse model to improve generalization to unseen speech classification tasks. Rather than allowing the model to generate freely in response to a prompt, the decoding is restricted to output from a predefined vocabulary of class names. For example, in an intent classification task, the model would be constrained to only generate intent labels such as *"play_radio"*, *"datetime_query"* or *"cooking_recipe"*. By limiting the output space, the model is more likely to produce the desired class label rather than unrelated text.

We meticulously benchmark the model's performance on close-ended tasks, such as a diverse set of classification tasks, that have a pre-defined set of finite class labels. To understand the influence of the instruction prompts, we divide this study into two parts: (1) where we only provide the class labels in the prompt, and (2) where we provide an accompanying description of each class label in the prompt. We ensure that none of these class labels were seen during training, and hence these are all novel tasks for the model. Further, we evaluate the efficacy of employing constrained decoding in each of these two parts, as the class labels are known to us beforehand. Note here that the SL task can be considered a harder task as the model has to correctly classify a slot label as well as identify the corresponding slot value from the speech. Hence, we report both, the SLU-F1 metric as well as the SD-F1 (Slot label Detection) metric for SL. The results of this study are presented in Table 7.

We observe that including descriptions in the prompt has inconsistent results, which can be attributed to the quality and subjectivity of the descriptions provided in the prompt, especially as these descriptions were not seen during training. However, we see that constrained decoding improves upon the results in all cases, and most significant gains are observed only when descriptions are provided with constrained decoding. This indicates that providing descriptions indeed steers the model towards better comprehension of the task semantics, but only constrained decoding is able to objectively prune the noise introduced by any prompt bias. This phenomena is further revealed in the SL task, where the SLU-F1 has a lower absolute value compared to SD-F1, as the SLU-F1 metric incorporates both slot label and slot value, whereas constrained decoding can only be applied to the slot label (hence the higher SD-F1). Similarly, for a completely unseen task of Domain Classification (DC), where the goal is to classify the content of the audio into five domains like healthcare, technology etc, we observe a strong performance of 62% accuracy with constrained decoding.

4.3.2 Joint Decoding

Certain SLU tasks require the model to understand the semantics of the audio or perform a operation on the content of the audio. For example, KWE task is about extracting important keywords from

the ASR hypothesis of the audio. Since this is a multi-step reasoning process for the model, we take inspiration from the existing work [41] on Chain-of-Thought (CoT) prompting. We train our model to first decode the ASR hypothesis of the audio, followed by the output of the task. The prompts used for the joint elicitation of ASR hypothesis and the task output are described in the Table 8. For a representative set of SLU tasks including IC, KWE and ER, we re-train the Task-FT models by adding a small portion of such multi-step examples along with single-task examples. We compare the results with and without joint decoding with ASR hypothesis in the Table 9.

Task	Instruction	Prediction
KWE	Perform the following audio-based tasks in the order as described. === Task: ASR === Perform speech recognition using the preceding audio. === Task: KWE === Identify significant keywords in the provided audio. Make sure to format the output as "ASR: KWE: "	ASR: paris is the capital of france KWE: paris, france
ER	Perform the following audio-based tasks in the order as described. === Task: ASR === What is being said in the audio? === Task: Emotion === Classify the tone of the speaker as happy, sad, angry or neutral Make sure to format the output as "ASR: Emotion: "	ASR: can you shut up for a while Emotion: angry

Table 8: Example prompt for elicitation of compound goals for KWE and ER task

Table 9: Results on compound goal experiments when decoding performed with (w/) and without (w/o) ASR.

			Joint Decoding		
Task	Dataset	Metric	w/o	w/	
IC	SLURP	ACC↑	90.4	92.2	
KWE	MCV Vox	F1↑	46.9 53.1	49.5 56.7	
ER	MSP	UAR↑	64.5	64.7	

The results in the table showcase that augmenting the training data with compound goals helps to improve the performance for all three tasks. The improved performance can be attributed to the possibility of self-attention on the already decoded ASR hypothesis in the decoder of our multimodal model. Further, such multi-step training examples brings out the true multimodal capabilities of the model to successfully complete the combination of tasks. Further, such a paradigm can help save crucial inference latency by using a single call of the large multi-modal model for obtaining both the transcript and the task output. A more detailed analysis on understanding the benefits of joint decoding will be conducted in future work.

5 Related Work

Multi-task learning. Prior studies have shown that a single deep learning model is capable of jointly learning multiple large-scale tasks across different domains [42]. The key idea in multi-task learning is to leverage shared representations across related tasks to improve overall generalization and efficiency. Following this approach, the T5 model [43] frames all text tasks as text-in to text-out, using a unified text-based framework that facilitates shared representations across textual tasks. Similarly, SpeechNet [44] and SpeechT5 [19] leverage a shared encoder-decoder framework to jointly model speech and text modalities spanning 5 to 6 tasks like TTS, ASR, and Voice Conversion (VC). VIOLA [15], a single auto-regressive Transformer decoder-only network, unifies various cross-modal speech and text tasks as a conditional codec language model via multi-task learning. Whisper [20] also employs large-scale multi-task learning, training on related speech tasks including language identification, speech recognition, and translation. In this work, SpeechVerse utilizes multi-task

Task	Instruction	Prediction
ASR	Transcribe the preceding audio	turn on the radio now
	What is being said in the preceding audio?	turn on the radio now
ST	Translate the english audio to german	schalten sie jetzt den radio auf
	Generate french translation for the english audio	mettez le radio à l'onder maintenant
IC	The previous audio needs to be mapped to exactly one of the following intents: - datetime_query: user asks about date, time, schedules, etc; - qa_definition: user wants to ask for general fact-based questions to receive definitions, explanations, descriptions, etc; - calendar_remove: user wants to remove calendar events by voice; - play_radio: user wants to request playback of radio, stations, etc;	play_radio
SF	Identify any of the following slots present in the speech: - date: any reference to a date, month or day of the week; - place_name: any reference of a place e.g., berlin, new york etc.; - person: any reference of a person; - time: any reference to time e.g., three am, two thirty etc.;	time = now;
KWE	Identify important keywords in the preceding recording	radio
KWS	Is the word 'radio' used in the audio?	yes
ER	Detect the primary emotion conveyed in this audio by the speaker's tone - is it happiness, sadness, anger, or neutral?	neutral
ASC	Classify the sentiment of the speaker into one of the following - positivity, negativity, or neutrality	neutral
AC	Analyze the speaker voice and figure out their accent from one of American, Indian, Australian, Canadian or British.	American
SC	How many distinct speakers are there in this audio clip.	one
SNS	Is their speech in the preceding audio or not?	speech

Table 10: Qualitative examples of output from all the training tasks on a audio file with transcription "turn on the radio now"

training to transfer knowledge between several related tasks while using natural language instructions to perform each task. Unlike prior work that generated text, speech, or both, our method focuses solely on producing textual output, while taking in audio and text instructions.

Multimodal Large Language Models. Prior work on multimodal LLMs has focused primarily on tasks involving images, such as image generation, visual question answering, and image captioning [4, 9, 45, 46]. Multimodal models incorporating modalities like audio and speech have received relatively less attention compared to vision-and-language models [47-49]. However, there has been growing interest in augmenting large language models with audio data, leading to several proposed approaches [8, 14, 17, 18, 50-52]. SpeechGPT [18] proposed a multimodal LLM combining discrete units of HuBERT with an LLM to solve few understanding tasks like ASR, Spoken QA as well as generation tasks like TTS. [17] introduces the novel capability of zero-shot instruction-following for more diverse tasks such as dialog generation, speech continuation and Question Answering. Most recently, [16] proposed Qwen-Audio, a large-scale audio-language model trained using a multi-task learning approach to handle a diverse range of tasks across various audio types including human speech, natural sounds, music, and songs. Qwen-Audio employs a single audio encoder to process various types of audio whose initialization is based on the Whisper-large-v2 model [20] and performs full finetuning. In contrast, our work utilizes two frozen pretrained models, one each for speech encoder and text decoder to retain their intrinsic strengths. Also, we utilize 30+ instructions for each task during training for improved generalization whereas [17] uses a single fixed instruction. Additionally, SpeechVerse incorporates multi-task learning and instruction finetuning in a single training stage.

6 Conclusion

In this work, we propose SpeechVerse, a multimodal framework that enables LLMs to follow natural language instructions for performing diverse speech processing tasks. Through supervised instruction finetuning and combining representations from frozen pre-trained speech and text foundation models, SpeechVerse achieves strong zero-shot generalization on unseen tasks. Extensive benchmarking against conventional baselines show SpeechVerse's superiority on 9 out of 11 tasks, demonstrating its formidable instruction following capability. Crucially, SpeechVerse maintains robust performance on out-of-domain datasets, unseen prompts, and even unseen tasks. This highlights the efficacy of our proposed training methodology in imbuing the model with a generalizable skill for mapping text-based instructions to speech processing outputs. Moving forward, we aim to expand Speech-Verse's capabilities to follow even more complex instructions and generalize to new domains. By separating task specification from model design, SpeechVerse represents a versatile framework that can dynamically adapt to new tasks through natural language without retraining.

Limitations

While this work demonstrated strong instruction following capabilities for the multitask SpeechVerse model across a variety of tasks, some limitations remain. The study relied on a single underlying LLM architecture (FlanT5) rather than exploring more recent models tailored for instruction following. Additionally, there is a trade-off between generalized capabilities on unseen tasks versus specialized performance on original training tasks that poses challenges for a single multitask model. While the model showed promise in handling diverse unseen tasks, its limitations were not fully characterized across the wide scope of possible instructions and the performance on these unseen tasks is not quantitatively measured.

Ethics Statement

All speech datasets we use have anonymous speakers. We do not have any access to nor try to create any PII (Personal Identifiable Information) of speakers, and our model neither identifies speakers nor uses speaker embeddings. Most of the work used public open-source datasets for both training and testing. The in-house datasets used for pre-training Best-RQ encoder and SNS task are collected via third-party speech data vendors. No additional data collections made concerning to the work carried in this paper.

Table 11: Various	hyper-parameters	for our models
-------------------	------------------	----------------

Parameter	Multitask-WLM	Multitask-BRQ
Audio encoder	WavLM-Large	Best-RQ
LLM	Flan-T5-XL	Flan-T5-XL
Convolution blocks	2	2
Kernel sizes	[3, 3]	[3, 3]
Strides	[2, 2]	[2, 1]
Audio encoder ampling rate	50Hz	25Hz
Down-sampling factor	4x	2x
# parameters	2.9B	3.2B
# trainable parameters	28.3M	26.8M
LoRA rank(r)	16	16
Learning rate	0.001	0.005
Warm-up steps	100	50000
Effective batch size	768	2048

A Appendix

A.1 Audio Encoder Pre-training

Our audio encoder is a 24-layer Conformer model with feature dimension of 768 and attention head of 8. The total number of parameters of this encoder model is 300M. We adopt the BEST-RQ [33] method, which pre-trains the model to predict the masked speech signals with labels generated from a random-projection quantizer. The quantizer projects the speech inputs with a randomly initialized matrix, and performs a nearest-neighbor lookup in a randomly-initialized codebook. Neither the projection matrix nor the codebook is updated during pre-training. We build an internal pre-training dataset containing 300K hours English audios. The pre-training uses mask span of 10 with total effective masking ratio about 40%. The learning rate schedule follows the transformer learning rate schedule with peak value of 0.0005 and warm-up of 50K steps. AdamW optimizer is adopted with weight decay of 0.01. Since the encoder has 4 times temporal-dimension reduction, the quantization with random projections stacks every 4 frames for projections. We use 16 individual codeboooks, where the vocab size of each codebook is 8192 and the dimension is 16. The model is pre-trained for 500K steps in total.

A.2 Hyper-parameters

We train all our models on a cluster of machines with 8 A100 GPUs, each having 40GB of memory. Pytorch Lightning framework³ is used for our implementation. A 5% subset of the complete training dataset for a model is used as a validation set to choose the important hyper-parameters. For the multi-task models, the sample weights for each dataset are also chosen using this validation set. Further, all models are trained till the validation loss converges and it does not improve for 5 consecutive epochs. The details of the learning rate, warmup steps, batch size for the Multitask-WLM and Multitask-BRQ are summarized in the Table 11. To adhere to memory constraints of the GPUs, we filter out any training sample where the sequence length of the audio is greater than 900 or the target label is greater than 600. Since, the WavLM Large samples audio features at 50Hz rate, we use two successive 1-D convolution blocks (kernel size=3, stride=2) for the Task-FT and Multitask-WLM model to downsample the audio four times and achieve the desired sampling rate of 12.5Hz. For BestRQ-based audio encoder, the sampling rate is 25Hz and hence the stride of the second convolution block is set to 1 to ensure the output sampling rate is 12.5Hz.

A.3 Tasks

We provide the details about our training tasks below as well as provide some qualitative examples in the Table 10 to better understand the tasks.

ASR: We use a combination of 5 publicly available datasets for the ASR task, which totals to 3k hours of paired audio and text data. We evaluate performance on the standard benchmarks for ASR.

ST: We train our models to predict translations in multiple different languages from the audios recorded with English speech. The tokenizer of the backbone LLM limits the choice of what can be a potential target language. For our case, we train and evaluate on German, French, and Romanian

³https://www.pytorchlightning.ai

translations from the EuroParl dataset [53]. We also augment the training data with German and Catalan translations from the CoVost2 [28] dataset .

IC/SF: We train and evaluate our models on a subset of the SLURP dataset [25] that consists of 10 intent classes and 4 slot labels. This also allows us to study the generalization ability of our models to unseen class labels and we separately study it in the Section 4.2. The intent classes and slot labels that are chosen for the "seen" subset are the ones that occur most frequently in the training data. The training prompt used for this task is designed to contain the description of each class label.

KWE: The goal of this task is to identify important keywords in the content of the speech in the audio. Since no publicly available dataset exists for this task, we synthetically extract keywords from the ground truth transcripts using a text-based keyword extraction model⁴. These are then used as labels for training and evaluating our models.

KWS: This is a binary classification task to detect whether a specified keyword was spoken in the audio or not. We create positive samples by randomly selecting keywords from the ground truth transcripts and negative samples by choosing a keyword that does not appear in the transcript. Positive and negative examples are created in 70-30 ratio respectively for both training and evaluation.

ER: For emotion recognition, we classify speech into one of four main emotion classes: neutral, happy, sad, and angry, chosen based on the availability of the training samples in the MSP-Podcast v1.11 dataset [54]. We report metrics on the corresponding four-emotion subset of the Test1 split of the dataset.

ASC: For audio sentiment classification, we classify speech as positive, negative, or neutral in sentiment. The sentiment labels were obtained by thresholding the valence scale (annotated from 1 to 7) with 3 and 5. We train on the entire training split of the MSP-Podcast v1.11 dataset, and evaluate on the corresponding Test1 split.

SC: For speaker counting, we identify whether one or two speakers are present. We train on segments from Fisher dataset transcripts [29, 30] with one or two speakers, and evaluate on the Fisher test split used in [55].

AC: We train our models to classify speech into five accents of English language: Canadian, Indian, Australian, British, and American, using metadata from the Mozilla Common Voice dataset.

SNS: In this task, we identify whether speech is present in the audio. We collect a diverse set of audios with and without speech for training our models and evaluate them on a combination of speech segments from Hub5 [56] dataset and held-out non-speech segments in our in-house collection.
