Abstract

The rapid development of domain-specific frameworks has presented us with a significant challenge: The current approach of implementing solutions on a case-by-case basis incurs a theoretical complexity of O(M×N), thereby increasing the cost of porting applications to different hardware platforms. To address these challenges, we propose a systematic methodology that effectively bridges the gap between domain-specific frameworks and multiple hardware devices, reducing porting complexity to O(M+N). The approach utilizes multi-layer abstractions. Different domainspecific abstractions are employed to represent applications from various domains. These abstractions are then transformed into a unified abstraction, which is subsequently translated into combinations of primitive operators. Finally, these operators are mapped to multiple hardware platforms. The implemented unified framework supports deep learning, classical machine learning, and data analysis across X86, ARM, RISC-V, IoT devices, and GPU. It outperforms existing solutions like scikit-learn, hummingbird, Spark, and pandas, achieving impressive speedups: 1.1x to 3.83x on X86 servers, 1.06x to 4.33x on ARM IoT devices, 1.25x to 3.72x on RISC-V IoT devices, and 1.93x on GPU. The source code is available at <https://github.com/BenchCouncil/bridger.git>.

Keywords: Deep Learning, Classical Machine Learning, Data Analysis, Runtime System

1 Introduction

[∗]Corresponding author.

Different application domains exhibit distinct characteristics in terms of data and computation. In deep learning (DL), tensors are prevalent, and iterative processes driven by backpropagation are essential [\[80\]](#page-14-0). Classical machine learning

(CML) primarily deals with arrays, although certain algorithms can handle tables and tensors as well. CML also involves iterative processes, but they are not specifically tied to backpropagation. Data analytics (DA) mainly revolves around tables and arrays, with computations that do not necessarily require iteration.

To cater to the specific requirements of each domain, provide user-friendly interfaces, and promote code reuse, current high-level applications often rely on domain-specific frameworks. Some popular frameworks include TensorFlow [\[5\]](#page-12-0), PyTorch [\[62\]](#page-13-0), and Mxnet [\[16\]](#page-12-1) for DL; scikit-learn [\[63\]](#page-13-1), Spark MLlib [\[52\]](#page-13-2), and XGBoost [\[15\]](#page-12-2) for CML; and pandas [\[50\]](#page-13-3), Spark [\[88\]](#page-14-1), and Dask [\[69\]](#page-13-4) for DA. These frameworks enable developers to work efficiently within their respective domains.

The rapid development of domain-specific frameworks has presented us with a significant challenge: the current approach of implementing solutions on a case-by-case basis incurs a theoretical complexity of O(M×N), thereby increasing the cost of porting applications to different hardware platforms. As depicted in Fig. [1a,](#page-1-0) we can observe the existence of numerous domain-specific frameworks in the domains of DL, CML, and DA. However, these frameworks often lack comprehensive support for the wide range of underlying hardware options.

Frameworks like scikit-learn and pandas, which are widely utilized in CML and DA, are primarily designed for hardware with mature software ecosystems such as X86 and ARM. Consequently, they may not possess the necessary support and optimizations for emerging hardware architectures like RISC-V, GPUs, and Internet of Things (IoT) devices.

This gap poses challenges for both software and hardware utilization. From a software perspective, the migration of

(a) Current domain-specific frameworks lack support and optimizations for diverse hardware devices. Case-by-case implementations have a complexity of O(M×N).

(b) We use domain-specific abstractions and unified abstractions to bridge applications and hardware, reducing porting complexity from $O(M\times N)$ to $O(M+N)$.

Figure 1. We propose a method to systematically bridge the gap between domain-specific frameworks and multiple hardware devices.

applications to different hardware platforms becomes significantly challenging and costly. On the hardware side, emerging hardware devices face limitations in their development due to inadequate software ecosystems.

Additionally, domain-specific frameworks exist in isolation, with the progress made in one application domain unable to be shared with others, resulting in a significant amount of duplicated work. DL has garnered significant attention and investment, benefiting from relatively robust hardware support and optimizations [\[18,](#page-12-3) [23,](#page-12-4) [53,](#page-13-5) [55,](#page-13-6) [66,](#page-13-7) [74,](#page-13-8) [76,](#page-14-2) [87,](#page-14-3) [89\]](#page-14-4). However, CML and DA have not received as much attention. They have limited hardware support and are unable to leverage the advancements in the DL domain.

This paper proposes a systematic methodology for constructing a unified framework that bridges the gap between multiple domain-specific frameworks and diverse hardware devices. The methodology outlined in Fig. [1b](#page-1-0) demonstrates

how this approach reduces the complexity of porting applications to different hardware platforms, achieving a complexity of O(M+N). It employs multi-layer abstractions: various domain-specific abstractions are used to represent applications from different domains, which are transformed into a unified abstraction, then lowered to the combinations of primitive operators that are finally mapped to multiple hardware platforms. It utilizes domain-specific abstractions to support diverse application domains, addresses portability issues through unified abstraction, leverages existing frameworks and compilers to reduce engineering costs, and incorporates multi-level optimizations to guarantee performance. A unified framework is implemented to support high-level application domains, including DL, CML, and DA, and lowlevel hardware devices, such as X86, ARM, RISC-V, IoT devices, and GPU.

This paper makes the following contributions:

- We present a systematic methodology for constructing a unified framework that effectively bridges the gap between domain-specific frameworks and hardware devices. This methodology reduces the theoretical complexity of porting applications from $O(M\times N)$ to $O(M +$ N).
- We design a unified framework that supports three application domains including DL, CML, and DA on various hardware devices such as X86, ARM, RISC-V, IoT devices, and GPU.
- We implement our work on top of TVM and LLVM, support a broader range of hardware, and achieve a speedup of 1.1x to 3.83x on X86 servers, 1.06x to 4.33x on ARM IoT devices, 1.25x to 3.72x on RISC-V IoT devices, and 1.93x on GPU, compared to existing solutions such as scikit-learn, hummingbird, Spark, and pandas.

The remainder of the paper is organized as follows. Section [2](#page-1-1) introduces the challenges. Section [3](#page-3-0) introduces the method. Section [4](#page-5-0) details the design and implementation. Section [5](#page-8-0) showcases the experimental results. Section [6](#page-11-0) discusses related work. Finally, we conclude in Section [7.](#page-11-1)

2 Challenges

To facilitate the efficient execution of diverse applications from different domains across multiple hardware platforms, three main challenges need to be addressed: portability, performance, and expressiveness. Section [2.1](#page-1-2) introduces portability, Section [2.2](#page-2-0) introduces performance, Section [2.3](#page-3-1) introduces expressiveness.

2.1 Portability

Portability refers to the ability to transfer a program from one hardware environment to another [\[64\]](#page-13-9), and the primary factors limiting portability are hardware differences such as architecture and instruction sets. Efficiently supporting complex applications on diverse and significantly different hardware has always been a hot topic in computer science.

In the early days, developers primarily used assembly language to develop programs on a specific hardware platform [\[10,](#page-12-5) [83\]](#page-14-5), without considering portability. Early compilers [\[7,](#page-12-6) [71,](#page-13-10) [82\]](#page-14-6) could translate high-level languages into assembly code, but they were specific to a particular hardware platform and lacked portability. With the increasing variety of hardware types, the case-by-case implementation could no longer meet the users' demands, and the portability issue entered the researchers' view.

In the late 1970s, PQCC [\[11,](#page-12-7) [13,](#page-12-8) [45,](#page-13-11) [84\]](#page-14-7) introduced a twostage structure. The frontend analyzes syntax and semantics to generate Intermediate Representation (IR), and the backend reads the IR to generate executable code. PQCC allowed the same code to run on multiple hardware platforms, ensuring portability. Subsequent compilers such as GCC [\[72\]](#page-13-12) and LLVM [\[44\]](#page-13-13) introduced a middle-end between the frontend and backend, forming a three-stage structure. They support more programming languages and hardware platforms and introduce more optimization techniques.

Looking back at the history of compiler development, we can find that the introduction of the two-stage structure and unified IR marked significant milestones. When it comes to supporting M programming languages on N hardware platforms, implementing programming language on hardware case-by-case leads to a complexity of $O(M \times N)$. By utilizing a unified IR, where various programming languages can be translated into the IR and then used to generate executable code for different hardware platforms, the complexity reduces to $O(M + N)$. The introduction of the IR bridges the gap between source code and hardware, significantly reducing porting complexity and engineering costs, and finally improving portability.

General-purpose compilers allow users to develop programs and generate executable code for different hardware platforms, effectively addressing the issue of portability. However, they lack domain-specific information and require users to perform domain-specific optimizations. Additionally, users need to implement algorithms from scratch at a low level, which can be quite labor-intensive. With the rapid development of emerging application domains such as DL, CML, and DA, users pay more attention to adapting high-level applications and innovating algorithms, hoping to reuse underlying implementations and optimizations. General-purpose compilers cannot fully meet these user needs. As a result, many domain-specific frameworks have emerged. They encapsulate algorithms specific to a particular domain, hiding the low-level implementation details, and making it easier for users to utilize. Consequently, these frameworks have gained popularity. However, this situation raises the issue of portability once again.

Porting a framework to a particular hardware typically involves two methods: leveraging high-performance libraries

like BLAS [\[8\]](#page-12-9) and cuDNN [\[19\]](#page-12-10), or utilizing compilers such as LLVM [\[44\]](#page-13-13). DL frameworks like TensorFlow and PyTorch use high-performance libraries to support hardware like X86, ARM, and GPUs. However, many hardware devices, such as numerous IoT devices, lack the necessary libraries required by these frameworks. DL compilers like TVM support such hardware through compilation, by generating LLVM IR and utilizing LLVM to support them. However, CML and DL frameworks such as scikit-learn and pandas primarily rely on libraries and are mainly fit for hardware with mature ecosystems like X86 and ARM, while lacking support and optimizations for emerging hardware like RISC-V, GPUs, and IoT devices.

2.2 Performance

Performance is also an important challenge, especially for latency-sensitive and resource-constrained tasks. To ensure performance, multiple levels need to be considered.

At the highest level, the characteristics of the application domain need to be analyzed to fully explore optimization opportunities based on their features. Take DL as an example. Many operators have data dependencies and their mathematical properties ensure that their fusion does not affect the results, leading to operator fusion optimizations [\[56,](#page-13-14) [90,](#page-14-8) [91\]](#page-14-9). Certain subgraphs in the computational graph can be transformed equivalently, suitable for different scenarios, which gives rise to graph substitutions replacing optimizations [\[28,](#page-12-11) [37,](#page-12-12) [48\]](#page-13-15). Data can have different layout formats, such as NCHW, NHWC, and NCHWc, which are suitable for different workloads and hardware, resulting in data layout transformation optimizations [\[47,](#page-13-16) [86\]](#page-14-10).

At the lowest level, it is crucial to fully leverage hardware features, including processor architecture and instruction sets, parallelism, and memory hierarchy. Hardware-related optimizations include loop transformation [\[9,](#page-12-13) [12,](#page-12-14) [22,](#page-12-15) [30,](#page-12-16) [36,](#page-12-17) [41,](#page-12-18) [49,](#page-13-17) [51\]](#page-13-18), parallelization [\[39,](#page-12-19) [46,](#page-13-19) [68,](#page-13-20) [73\]](#page-13-21), vectorization [\[25,](#page-12-20) [57,](#page-13-22) [58\]](#page-13-23), among others.

In addition, many optimization techniques at the intermediate level are unrelated to the application and hardware but are relatively more generic, such as common subexpression elimination [\[20,](#page-12-21) [65\]](#page-13-24) and dead code elimination [\[42,](#page-13-25) [85\]](#page-14-11). To ensure performance, optimization methods at all these levels should not be overlooked.

High-performance libraries encapsulate common computations and provide user-friendly programming interfaces after manual tuning. Many hardware vendors also provide high-performance libraries targeting their hardware [\[1–](#page-12-22)[3,](#page-12-23) [19,](#page-12-10) [77\]](#page-14-12). These high-performance libraries cover low-level and intermediate-level optimizations but do not involve domainspecific optimizations. Currently, many domain-specific frameworks call high-performance libraries and supplement them with domain-specific optimizations. The problem with highperformance libraries is that, on the one hand, they do not support comprehensive computations and often cannot meet

the requirements of high-level application domains. On the other hand, they have limited hardware support, lacking optimizations for many emerging hardware platforms.

General-purpose compilers like GCC and LLVM cover low-level and intermediate-level optimizations but do not involve domain-specific optimizations. They require highlevel frameworks to provide domain-specific optimizations. Currently, these three application domains do not directly utilize general-purpose compilers to support high-level applications but rather use them as backends to efficiently support diverse hardware platforms. However, the automatic optimizations of general-purpose compilers are not comprehensive, and they require optimization-related information from high-level frameworks.

DL frameworks like TensorFlow and PyTorch have unified intermediate abstractions that allow the reuse of many domain-specific optimizations. This enables them to fully leverage domain-specific features. The intermediate and low-level optimizations of these frameworks rely on highperformance libraries, facing challenges in optimizing for emerging hardware. DL compilers like XLA and TVM follow the same high-level optimizations but interface with generalpurpose compilers like LLVM at the lower level. They utilize these compilers for intermediate and low-level optimizations, supporting a wider range of hardware platforms compared to high-performance libraries and achieving better performance on some hardware.

CML frameworks like scikit-learn and Spark MLlib lack intermediate abstractions, and domain-specific optimizations are performed during algorithm implementations. This makes it difficult to reuse optimizations for different algorithms, which impacts performance and increases engineering costs. Intermediate and low-level optimizations rely entirely on high-performance libraries but are also limited by them.

DA frameworks like Spark and pandas have unified intermediate abstractions that allow the reuse of domain-specific optimizations to fully leverage domain-specific features. They also rely on high-performance libraries and are therefore constrained by them. In summary, ensuring performance across multiple hardware platforms is an important challenge, related to multi-level optimizations.

2.3 Expressiveness

To support high-level applications, the framework needs to have strong expressiveness, which involves clear and accurate data abstraction, computation abstraction, and representation of data flow and computation dependencies.

Data abstraction encompasses the comprehensive representation of the data used in the applications and the effective organization and manipulation of this data. Computation abstraction requires an accurate description of the computations within the applications, breaking down complex applications into simpler and more manageable computational

units that can be combined. Data flow and computation dependencies are commonly represented using graphs, with the most common ones being data flow graphs [\[40\]](#page-12-24) and control flow graphs [\[6\]](#page-12-25).

Due to the variations in data and computations across different application domains, their data and computation abstractions differ as well. We discuss DL, CML, and DA separately. The data used in DL includes images, text, audio, and more. Most of these data types are represented, stored, and processed using tensors, which are the fundamental data abstraction for DL. In DL, neural network models usually comprise multiple layers, each performing various computational operations such as convolution, matrix multiplication, and activation functions. These operations, known as operators, serve as the fundamental computation abstraction. High-level applications are built by combining these operators in different ways. Computational graphs, represented as directed acyclic graphs (DAGs), are used to represent the data flow and computation dependencies. In these graphs, nodes represent operators, and edges represent tensors.

The data used in CML includes tables, text, images, and more. The data abstraction in CML is relatively complex and includes scalars, matrices, arrays, and tables. Applications in CML are composed of multiple models organized in pipelines, including data preprocessing, linear models, trees, forests, and more. These models are relatively complex but are still considered as the minimum units for implementation and scheduling. Pipelines are represented using DAGs, where nodes represent models and edges represent different types of data.

DA primarily deals with data such as tables, text and time series. The data abstraction in DA includes relational tables, scalars, and arrays. Applications in DA are composed of pipelines that combine various operators, including relational operators like selection, projection, and join, as well as basic mathematical and statistical operators like matrix inverse and covariance. These operators serve as the computation abstraction. Pipelines in DA are represented using DAGs, where nodes represent operators and edges represent data.

We find that the data flow and computation dependencies in these application domains can all be represented using DAGs. However, the data and computation abstractions differ significantly. The challenge lies in how to represent applications from these different domains and how to represent cross-domain applications effectively.

3 Methodology

This section introduces the methodology to systematically bridge the gap between domain-specific frameworks and multiple hardware devices, as shown in Fig. [1b.](#page-1-0) We use domain-specific abstractions and unified abstractions to bridge applications and hardware, reducing porting complexity from $O(M\times N)$ to $O(M+N)$.

3.1 Address Portability Issues through Intermediate Abstraction

Looking back at the development history of general-purpose compilers and the ecosystems of the three application domains, it can be observed that the primary method for addressing portability is through the introduction of intermediate abstractions, bridging the gap between high-level application domains and low-level hardware, thus reducing the porting costs from $O(M \times N)$ to $O(M + N)$. Based on a similar concept, we propose a unified intermediate abstraction for the three application domains, which can represent highlevel algorithms and is then mapped to various low-level hardware platforms.

3.2 Propose Domain-specific Abstractions and Unified Abstraction for High-level Applications

The intermediate abstractions need to be able to represent applications from different domains. We propose a two-layer abstraction: domain-specific abstractions for interfacing with application domains, which are then transformed into a unified abstraction for interfacing with hardware. The unified abstraction can also be used to represent cross-domain applications.

First, we introduce the unified abstraction, which requires the exploration of commonalities in three application domains. The biggest commonality among DL, CML, and DA is that they can all be represented as DAGs to depict data flow. This forms the basis for cross-domain pipelines and forms the establishment of a unified abstraction. Therefore, we propose a unified abstraction based on DAG.

The meanings of nodes and edges in the corresponding DAGs of the three domains differ due to the differences in data and computation abstractions. To accurately represent applications from the three domains, we propose domainspecific abstractions for each domain. As shown in Table [1,](#page-5-1) for DL, data mainly consists of numerical tensors and the computation abstraction treats DL operators as the smallest unit, with algorithms represented as the combinations of operators. We adopt the existing DL abstractions, using tensors as the data abstraction and DL operators as the computation abstraction.

For CML, data mainly consists of numerical scalars, arrays, and tables, all of which can be converted to tensors directly. However, there is no suitable computation abstraction. Models are implemented case by case, and there are a large number of models. The problem lies in computation abstraction. We use classical operator representation (COR) [\[79\]](#page-14-13) as the computation abstraction of CML. It represents CML models as combinations of assignment, exchange, basic arithmetic,

aggregation, comparison, and conditional operators. In summary, we use tensors as the data abstraction and COR as the computation abstraction for CML.

For DA, data structures include relational tables, scalars, and arrays, with both numerical and non-numerical data types. The computation abstraction in DA also treats operators as the smallest unit, and there are only a small number of operators. The problem lies in data abstraction. We use TensorTable [\[78\]](#page-14-14) as the data abstraction of DA, it stores data in a tensor format and can represent different data structures and data types mentioned above. In summary, we use TensorTable as the data abstraction and DA operators as the computation abstraction for DA.

With the above approach, appropriate domain-specific abstractions are constructed for different application domains. Subsequently, three domain-specific abstractions are transformed into the unified abstraction. The data abstraction of the unified abstraction includes tensor and TensorTable, while the computation abstraction includes DL operators, COR, and DA operators.

3.3 Reuse Existing Frameworks and Compilers to Reduce Engineering Cost

We use domain-specific abstractions and unified abstractions to represent high-level applications. However, to run multiple applications on different hardware devices, these abstractions need to be mapped to the hardware. We leverage existing frameworks and compilers to support multiple hardware platforms, thereby reducing the engineering cost. Due to the better portability of DL compilers compared with other domain-specific frameworks of three domains, we reuse DL compilers to support hardware such as X86, ARM, GPUs, and IoT devices. However, DL compilers also lack support for certain hardware platforms like RISC-V. Therefore, we introduce a low-level code generator to generate LLVM IR specifically for RISC-V and similar hardware, leveraging LLVM's support for these hardware. Additionally, DL compilers rely on auto-tuning for optimizations, which incurs high time costs and are not suitable for CML and DA. Therefore, we propose new optimization methods specifically for them.

3.4 Use Multi-level Optimizations to Guarantee Performance

To improve performance, it is necessary to fully utilize the characteristics of application domains and leverage hardware capabilities. Our work mainly includes two-level optimizations: graph-level optimizations and operator-level optimizations.

Graph-level optimization can be categorized into three types. Domain-specific optimizations are tailored to the characteristics of each application domain and are unique. To capture the domain-specific features, we propose domainspecific abstractions for the three application domains and

Table 1. The differences in Classical Machine Learning, Deep Learning and Data Analysis

	Deep Learning	Classical Machine Learning	Data Analysis	
Data Structure	tensor	scalar, array, table	relational table, scalar, array	
Data Type	numeric	numeric	numeric, non-numeric	
Computation Abstraction	Operators as the smallest unit;	No computation abstraction;	Operators as the smallest unit; Small number of operators	
	Algorithms represented as the	Case-by-case implementation;		
	combinations of operators	Large number of models		

conduct domain-specific optimization based on these abstractions, such as operator fusion and data layout transformation for DL, sparse operator replacing and data type rewriting for CML, as well as operator reorder and operator fusion for DA. After domain-specific optimizations, three domain-specific abstractions are transformed into a unified abstraction. The unified abstraction enables cross-domain optimizations for mixed workloads from three domains, primarily including cross-domain operator reorder and cross-domain operator fusion. Subsequently, generic graph-level optimizations are applied to the unified abstraction, such as constant propagation and common subexpression elimination.

After graph-level optimizations are completed, operatorlevel optimizations are performed. Operator-level optimization mainly consists of two types: hardware-agnostic optimizations such as constant folding and copy propagation, and hardware-specific optimizations such as loop transformation and vectorization. All those optimizations work together to guarantee performance.

4 The System Design and Implementation

This section illustrates the design and implementation. Section [4.1](#page-5-2) shows the design overview. Section [4.2](#page-5-3) introduces domain-specific abstractions and optimizations. Section [4.3](#page-6-0) introduces unified abstraction and optimizations. Section [4.4](#page-6-1) introduces primitive operator set. Section [4.5](#page-6-2) introduces code generation and operator-level optimizations. Section [4.6](#page-8-1) shows the implementation.

4.1 Design Overview

Fig. [2](#page-5-4) shows the design overview. The frontend is used to read models and pipelines from other frameworks and convert them to domain-specific abstractions. Cross-domain applications that use multiple frameworks are converted to many subgraphs and stitched together based on data dependencies. Domain-specific abstractions are used to represent different application domains, capturing their data and computation features. They are converted to a DAG-based unified abstraction, which is then mapped to the combination of primitive operators. Multi-level optimizations are performed for those abstractions, including domain-specific optimizations for domain-specific abstractions, cross-domain and generic graph-level optimizations for DAG-based unified abstraction,

Figure 2. Design Overview.

as well as operator-level optimizations for primitive operators. The backend is used to generate executable code. The runtime reads executable code and input data, running on multiple hardware.

4.2 Domain-Specific Abstractions and Optimizations

We use domain-specific abstractions to represent high-level applications, all of which are based on DAG, with different data and computation abstraction. For DL, we use tensors as the data abstraction and DL operators as the computation abstraction. For CML, we use tensors as the data abstraction and classical operator representation (COR) [\[79\]](#page-14-13) as the computation abstraction. COR uses the combinations of six categories of operators, namely assignment, swap, basic arithmetic, aggregation, comparison, and conditional operators, to represent widely-used CML algorithms, such as preprocessing algorithms, linear models, trees and forests, and SVMs. For DA, we use TensorTable [\[78\]](#page-14-14) as the data abstraction and DA operators as the computation abstraction. TensorTable represents relational tables as a combination of tensors and

dictionaries, by converting those non-numerical data into numerical data and using auxiliary dictionaries to preserve the mapping relations. TensorTable can also seamlessly encapsulate other data structures such as scalars and arrays. DA operators are all implemented based on TensorTable, including relational operators, covering selection, projection, join, group by, and aggregation, as well as basic mathematical and statistical operations.

We conduct domain-specific optimizations based on these abstractions to fully utilize the features of each domain, as shown in Table [2.](#page-7-0) Domain-specific optimizations for DL include operator fusion, data layout transformation, graph substitutions replacing, and tensor recomputation. Domainspecific optimizations for CML include sparse operator replacing, data type rewriting, and redundant operator elimination. Domain-specific optimizations for DA include operator reorder and operator fusion.

4.3 Unified Abstractions and Optimizations

After domain-specific optimizations, all three domain-specific abstractions are transformed into a unified abstraction. It's also based on DAG, with nodes representing operators and edges denoting data. Its data abstraction includes both tensor and TensorTable, and its computation abstraction includes DL operators, COR, and DA operators.

As shown in Table [3,](#page-7-1) unified abstraction enables many optimizations, including cross-domain optimizations and generic graph-level optimizations. Cross-domain optimizations cater to mixed workloads from three domains, primarily including cross-domain operator reoder and cross-domain operator fusion. Cross-domain operator reorder changes the order of operators from different domains which meet commutativity, to decrease computation. Cross-domain operator fusion merges operators from different domains into one operator, to reduce intermediate data. Generic graph-level optimizations include constant folding, constant propagation, copy propagation, common subexpression elimination, dead code elimination, and more.

4.4 Primitive Operator Set

After graph-level optimizations, the unified abstraction is mapped down to the combinations of operators. DL encom-passes over two thousand operators^{[1](#page-6-3)}, while CML and DA each involve dozens of operators. The cost of implementing and optimizing operators one by one is prohibitively high. Therefore, we construct a primitive operator set consisting of eighty operators, focusing on their implementations and optimizations. Algorithms used by high-level applications can be represented as the combinations of them. Subsequently, the primitive operator set is implemented, generating executable code tailored for multiple hardware platforms.

The process of constructing the primitive operator set is as follows:

(1) We summarize all required operators in DL, CML, and DA, totaling around 2300 operators. (2) We eliminate longtail operators that are rarely used and those various overloads for the same operators, reducing to around 300 operators. (3) We retain operators that cannot be formed by combinations of other operators or those whose performance is significantly lower when combined, resulting in 80 operators, as the primitive operator set. The final primitive operator set is shown in Table [4.](#page-7-2)

Primitive operators are primarily divided into eight categories: Injective operators perform identical computations on each element within a single tensor, including operations like modulus (mod), negation (negative), and absolute value (abs), among others. Element-wise operators perform operations between corresponding elements in two tensors, such as addition (add), subtraction (subtract), multiplication (multiply), division (divide), and so on. Reduction operators derive aggregated results from a single tensor across one or multiple dimensions. Examples include maximum value (max), minimum value (min), summation (sum), and mean computation (mean), among others. Index operators compute each element within a single tensor and return the corresponding index. Examples include returning indices for non-zero values (nonzero), returning indices for maximum values (argmax), and indices for minimum values (argmin), among others. Memory operators manage memory-related actions, such as reshaping (reshape), copying data (copy), transposing (transpose), and others. Key construct operators are used in join operations to build key-value indices, including inner_key_construct to construct keys for inner join, outer_key_construct to construct keys for outer join, and others. Special computation operators encompass complex and crucial computations like matrix multiplication (matmul) and convolution (conv). While these operations can be expressed as the combinations of injective, elementwise, and reduction operators, they are retained separately to ensure optimizations, especially for hardware-specific optimizations. Control operators represent control flow within computations, such as if condition (if then else) and loop.

4.5 Code Generation and Operator-level **Optimizations**

For primitive operators, we adopt scheduling techniques proposed by Halide [\[67\]](#page-13-26) and TVM to describe and optimize them. The utilized schedules are outlined in Table [5.](#page-7-3) Optimizations such as parallelization, memory hierarchy, and vectorization are employed based on hardware specifications to ensure performance. For hardware such as X86, ARM, and GPUs that are well supported by TVM, the code generation part of TVM is directly reused to generate executable code. To support more hardware platforms such as RISC-V, we supplement code generation modules specifically for them, which can

generate LLVM IR that can be further optimized and translated into executable code using LLVM. Parallelization is directly implemented using relevant APIs like llvm::parallel. Vectorization is achieved through hardware-specific LLVM intrinsics, for instance, $llvm.riscv.v$ for RISC-V vector extension instructions.

Regarding cache-related optimizations, since many hardware cannot directly manage various levels of cache, optimization is achieved by adjusting parameters within the

schedule, such as tile size and split size. We make cacherelated optimizations by solving a constrained optimization problem:

$$
argmin(max(\frac{DataMove_l}{BandWidth_l}))
$$

.s.t. $\forall l \in L \quad DataOccupy_l < Capacity_l$ (1)

The constraints ensure that the data occupation of each cache level is smaller than its corresponding cache capacity. The optimization objective is to minimize data movement time. The symbols are listed in Table [6.](#page-7-5)

During code generation, we make operator-level optimizations, mainly consisting of two types: hardware-agnostic optimizations and hardware-specific optimizations, as shown in Table [7.](#page-8-2) Hardware-agnostic optimization includes inlining, constant folding, constant propagation, copy propagation, common subexpression elimination, dead code elimination, and more. Hardware-specific optimization includes loop unrolling, loop fusion, loop splitting, blocking, data alignment, parallelization, vectorization, tensorization, register allocation, instruction scheduling, and more. Many graph-level

Table 7. Operator-level Optimizations for Primitive Operators

Application Models and Pipelines From Other Frameworks

Unified Abstraction & Optimization

Figure 3. System Architecture.

optimizations and operator-level optimizations share similar names and approaches, but they are targeted at different entities (graphs and operators) and have significant differences in implementations.

Finally, we deploy executable code on lightweight runtime to run DL, CML, and DA applications, as well as cross-domain mixed applications, on multiple hardware platforms.

4.6 Implementation

The system architecture is shown in Fig. [3.](#page-8-3) The blue part represents the components reused from TVM, the green part represents the components reused from LLVM and CUDA, and the yellow part represents our contribution. At the top level, there are application models and pipelines from other frameworks, which are transformed into three domain-specific abstractions using APIs like from_pytorch and from_sklearn. After domain-specific optimizations, the three domain-specific abstractions are transformed into a DAG-based unified abstraction. The unified abstraction, after graph-level optimization, is mapped down to the combinations of primitive operators. The primitive operators are implemented using TVM, adopting the decoupled compute/schedule principle [\[17,](#page-12-26) [67\]](#page-13-26), striving to reuse code as much as possible while ensuring comprehensive optimization. Hardware-agnostic and hardware-specific optimizations are performed at the operator level. Subsequently, executable code is generated for multiple backends. For hardware such as X86, ARM, and GPUs that are well supported by TVM, the code generation part of TVM is directly reused to generate executable code. To support more hardware platforms such as RISC-V, we supplement code generation modules specifically for them, which can generate LLVM IR that can be further optimized and translated into executable code using LLVM. We make cache-related optimizations by solving a constrained optimization problem instead of auto-tuning used by TVM, better fitting for CML and DA workloads. Finally, the generated code runs on lightweight runtime which is implemented based on TVM runtime and executes on multiple hardware platforms.

5 Evaluation

This section summarizes the evaluation. Section [5.1](#page-8-4) shows the experimental setup. Section [5.2](#page-8-5) evaluates the coverage of primitive operators. Section [5.3](#page-9-0) evaluates the performance on diverse hardware.

5.1 Experimental Setup

We evaluate the performance on X86 server, ARM IoT device, RISC-V IoT device, and GPU. We deploy a server node equipped with two Xeon E5-2620 V3 (Haswell) CPUs, an Nvidia Titan RTX GPU, and 64 GB memory to conduct the experiments on x86 server and GPU. Each CPU contains 6 physical cores with hyper-threading. The GPU contains 4608 CUDA cores and 24 GB memory, CUDA version is 10.2. The operating system used is Ubuntu 16.04. The ARM IoT device used is the Raspberry Pi 4B, which features a quad-core Cortex-A72 CPU and 4GB memory. It runs on the Raspbian 10 operating system. The RISC-V IoT device employed is the VisionFive 2, equipped with a quad-core JH7110 CPU and 8GB memory. It runs on the Debian 12 operating system. The software utilized includes TVM 0.15, scikit-learn 1.1.2, Intel(R) Extension for Scikit-learn 2021.20220215.162512, hummingbird 0.3.1, CMLCompiler 1.01, pandas 1.3.5, Spark 3.3.0, and MonetDB 11.39.17.

5.2 The Coverage of Primitive Operators

First, we analyze the coverage of the primitive operator set. To begin, we analyze the coverage within the DL domain. A set of 103 widely-used DL models is extracted from the

Figure 4. The coverage of primitive operators.

ONNX model repository^{[2](#page-9-1)}. Among them, 101 models were entirely composed of primitive operators, while only two models contained long-tail operators. Specifically, the ResNetpreproc model has the sequenc map operator, and BiDAF model has the category mapper, hardmax, and compress operators, which are long-tail operators. Next, we analyze the coverage within the CML domain. We extract 47 highfrequency models shared between two widely used frameworks scikit-learn and Spark MLlib. All these models can be entirely represented by primitive operators, without any occurrences of long-tail operators. Finally, we analyze the coverage within the DA domain. We analyze 22 DA pipelines from TPC-H^{[3](#page-9-2)}. All of them can be fully represented by primitive operators, without any long-tail operator occurrences. In summary, as illustrated in Fig. [4,](#page-9-3) 98% of the 103 DL models, all 47 CML models, and all 22 DA pipelines can be represented by the primitive operators. This demonstrates that the primitive operator set adequately covers the majority of scenarios in DL, CML, and DA applications.

5.3 Performance

This section compares the performance on various hardware platforms against existing frameworks. We test ten CML models and compare our work with sklearn, intel sklearn, CMLCompiler, and hummingbird. Use YearPrediction dataset [\[24\]](#page-12-27), which consists of 51,630 samples and 90 features. We test five DA operators and compare our work with MonetDB, Spark, and pandas. Use BIXI dataset [\[26\]](#page-12-28) at data scales of 1k, 10k, 100k, 1m, and 10m rows, and show their geometric means. All experiments are repeated five times, and the arithmetic mean is used as the final result.

Fig. [5](#page-10-0) displays the performance on x86 server. Our work achieves the best performance in 7 out of 10 tested CML models. CMLCompiler attains the best performance in 3 models, while sklearn, intel sklearn, and Hummingbird do not outperform in any algorithm. We achieve a 1.95x to 10.21x speedup compared with sklearn across 10 models, with an average speedup of 3.83. We achieve a 1.2x to 8.18x speedup compared with intel sklearn across 10 models, with an average speedup of 3.79. We achieve a 2.57x to 5.25x speedup compared with Hummingbird across 10 models, with an average

²<https://github.com/onnx/models>

speedup of 3.24. This is attributed to our better utilization of multi-core parallelism and SIMD instructions. We achieve a 1.11x to 3.25x speedup compared with CMLCompiler across 7 models, with an average speedup of 1.75. For algorithms like Binarizer, Normalizer, MinMaxScaler, and RobustScaler, which involve relatively simpler computations, where optimization space is limited, we do not exhibit significant speedup compared to CMLCompiler, but the performance difference remains within 5%. For more complex algorithms like LogisticsRegression, SGDClassifier, and ExtraTreeClassifier, where a larger optimization space exists, we showcase noticeable speedup due to the memory-related optimizations.

Our work achieves the best performance in 2 out of 5 tested DA operators. We achieve a 1.04x to 5.06x speedup compared with MonetDB across 4 operators, with an average speedup of 2.38. We achieve a 3.34x to 108.37x speedup compared with Spark across 5 operators, with an average speedup of 28.31. We achieve a 1.46x to 1.58x speedup compared with pandas across 2 operators, with an average speedup of 1.1. For the projection operator, we adjust the data layout, thus exhibiting weaker performance compared to pandas. However, this implementation ensures data locality, guaranteeing the performance of other operators. For inner join and group by operators, we showcase a 7% and 20% performance difference, respectively, which remains within an acceptable range. Overall, we achieve a noticeable speedup compared to MonetDB and Spark, and has its strengths compared to pandas.

Fig. [6](#page-10-1) illustrates the performance of ARM IoT devices. Our work outperforms across all 10 tested CML models. We achieve a 1.56x to 9.6x speedup compared with sklearn, with an average speedup of 4.33. Since sklearn's high-performance library lacks optimizations for ARM IoT devices, our work obtains a larger speedup on this device. We achieve a 1.13x to 2.98x speedup compared with CMLCompiler, with an average speedup of 2.1. Intel sklearn and Hummingbird do not support this device, their results are absent.

Our work achieves the best performance in 4 out of 5 tested DA operators. We achieve a 1.04x to 1.32x speedup compared with pandas across 4 operators, with an average speedup of 1.06. Except for the projection operator, which sacrifices some performance to ensure data locality, our work performs equally or better than pandas for the other operators. MonetDB and Spark do not support this device, their results are absent.

Fig. [7](#page-10-2) depicts the performance of RISC-V IoT devices. Our work outperforms across all 10 tested CML models. We achieve a 1.93x to 10.23x speedup compared with sklearn, with an average speedup of 3.72. We achieve a 1.02x to 4.32x speedup compared with CMLCompiler, with an average speedup of 2.03. Because TVM lacks optimization for RISC-V, CMLCompiler, reliant on TVM for multi-hardware support, exhibits poor performance on RISC-V, with some algorithms even slower than sklearn. However, our work

³<https://www.tpc.org/tpch/>

Figure 5. The performance on X86 server. The absent data means unsupported.

Figure 6. The performance on ARM IoT device. The absent data means unsupported.

Figure 7. The performance on RISC-V IoT device. The absent data means unsupported.

uses the code generator to optimize for RISC-V, resulting in a noticeable speedup compared to CMLCompiler. Intel sklearn and Hummingbird do not support this device, their results are absent.

Our work achieves the best performance in 4 out of 5 tested DA operators. We achieve a 1.09x to 2.14x speedup compared with pandas across 4 operators, with an average speedup of 1.25. MonetDB and Spark do not support this device, their results are absent.

Figure 8. The performance on GPU. The absent data means unsupported.

Fig. [8](#page-11-2) shows the performance on GPU. Our work achieves the best performance in 9 out of 10 tested CML models. We achieve a 1.16x to 3.47x speedup compared with Hummingbird across 8 models, with an average speedup of 1.93. All other frameworks cannot support GPU.

In summary, compared to state-of-the-practice and stateof-the-art frameworks, our work supports a broader range of hardware and achieves noticeable speedup on them, especially for devices lacking mature high-performance libraries.

6 Related Work

This section summarizes some typical related works based on their supported application domains, portability, performance, and methods.

Deep learning (DL) frameworks include TensorFlow [\[5\]](#page-12-0), PyTorch [\[62\]](#page-13-0), MXNet [\[16\]](#page-12-1), and Keras [\[33\]](#page-12-29). They are specifically designed for DL and leverage unified abstractions to make full use of domain-specific features and hardware, resulting in good performance. These frameworks rely on high-performance libraries such as Eigen [\[32\]](#page-12-30), BLAS [\[8\]](#page-12-9), and cuDNN [\[19\]](#page-12-10) to support hardware platforms like X86, ARM, and GPUs. However, they are unable to support hardware platforms that do not provide the required libraries.

DL compilers include XLA [\[4\]](#page-12-31), Glow [\[70\]](#page-13-27), Tensor Compre-hension [\[75\]](#page-13-28), and TVM [\[17\]](#page-12-26). Similar to DL frameworks, they focus on DL and ensure performance through multi-layer abstractions. They integrate with general-purpose compilers like LLVM [\[44\]](#page-13-13), using code generation to support a wider range of hardware platforms, resulting in better portability.

Classical machine learning (CML) libraries include LibLinear [\[27\]](#page-12-32), SVMlight [\[38\]](#page-12-33), and LibSVM [\[14\]](#page-12-34). They are dedicated to several CML models and achieve good performance by implementing and optimizing algorithms from scratch. However, their portability is limited.

CML frameworks include Scikit-learn [\[63\]](#page-13-1), Spark MLlib [\[52\]](#page-13-2), RapidMiner [\[35\]](#page-12-35), and Weka3 [\[31\]](#page-12-36). They implement and optimize algorithms at a higher level case-by-case while

leveraging high-performance libraries to support different hardware platforms. Their portability and performance have significant potential for improvement.

Data analysis (DA) frameworks include pandas [\[50\]](#page-13-3), Dask [\[69\]](#page-13-4), Hadoop [\[81\]](#page-14-15), and Spark [\[88\]](#page-14-1). They have domain-specific abstractions, leveraging high-performance libraries to support different hardware platforms. These frameworks exhibit good performance with moderate portability.

There are also efforts to support multiple application domains through two main approaches: extending existing frameworks and building from scratch for specific hardware. Databricks [\[21\]](#page-12-37) attempts to support both CML and DA in a DA framework, but it directly reuses existing abstractions, which are not suitable for DL's backpropagation and parameter iteration processes, leading to redundant computations and additional overhead that severely affect performance. Raven [\[61\]](#page-13-29) supports CML models in a DA framework, while H2O [\[34\]](#page-12-38), Weka3 [\[43\]](#page-13-30), and KNIME [\[29\]](#page-12-39) support DL models in CML frameworks. Hummingbird [\[54\]](#page-13-31) supports CML models on DL frameworks, but it lacks domain-specific optimizations. They all rely on reusing existing abstractions and invoking high-performance libraries, but cannot guarantee domain-specific optimizations, resulting in performance deviations. NVIDIA supports all three application domains on GPUs [\[19,](#page-12-10) [59,](#page-13-32) [60\]](#page-13-33). They achieve good performance by implementing and optimizing each domain's functionalities from scratch but lack portability to other hardware platforms.

Our work simultaneously supports all three application domains and provides support for a wider range of hardware platforms, ensuring both portability and performance.

7 Conclusion

This paper proposes a methodology for constructing a unified framework to bridge the gap between domain-specific frameworks and diverse hardware devices. The methodology leverages multi-layer abstractions, allowing applications from different domains to be represented using specific abstractions tailored to their respective fields. These abstractions are subsequently transformed into a unified abstraction, which is further translated into a minimum combination of primitive operators. Ultimately, these operators finally mapped to multiple hardware platforms. This methodology reduces the theoretical complexity of porting applications from $O(M\times N)$ to $O(M + N)$. A unified framework is implemented, supporting three application domains, including deep learning, classical machine learning, and data analysis on various hardware devices such as X86, ARM, RISC-V, IoT devices, and GPU. Compared to existing solutions such as scikit-learn, hummingbird, Spark, and pandas, it supports a broader range of hardware and achieves a speedup of 1.1x to 3.83x on X86 servers, 1.06x to 4.33x on ARM IoT devices, 1.25x to 3.72x on RISC-V IoT devices, and 1.93x on GPU.
