Abstract

Adapting pre-trained foundation models for various downstream tasks has been prevalent in artificial intelligence. Due to the vast number of tasks and high costs, adjusting all parameters becomes unfeasible. To mitigate this, several finetuning techniques have been developed to update the pre-trained model weights in a more resource-efficient manner, such as through low-rank adjustments. Yet, almost all of these methods focus on linear weights, neglecting the intricacies of parameter spaces in higher dimensions like 4D. Alternatively, some methods can be adapted for high-dimensional parameter space by compressing changes in the original space into two dimensions and then employing low-rank matrix decomposition. However, these approaches destructs the structural integrity of the involved high-dimensional spaces. To tackle the diversity of dimensional spaces across different foundation models and provide a more precise representation of the changes within these spaces, this paper introduces a generalized parameter-efficient fine-tuning framework, FLoRA, designed for various dimensional parameter space. Specifically, utilizing Tucker decomposition, FLoRA asserts that changes in each dimensional parameter space are based on a low-rank core space which maintains the consistent topological structure with the original space. It then models the changes through this core space alongside corresponding weights to reconstruct alterations in the original space. FLoRA effectively preserves the structural integrity of the change of original N-dimensional parameter space, meanwhile decomposes it via low-rank tensor decomposition. Extensive experiments on computer vision, natural language processing and multi-modal tasks validate FLoRA's effectiveness. Codes are available at https://github.com/SJTU-DeepVisionLab/FLoRA.

1 Introduction

The recent introduction of foundation models Brown et al. [2020], Kirillov et al. [2023], Devlin et al. [2018], Liu et al. [2019] has demonstrated unparalleled performance and potential across diverse domains in artificial intelligence. Traditionally, the adaptation of pre-trained models for downstream tasks is achieved through fully fine-tuning of all parameters Ma et al. [2024], Raffel et al. [2020], Qiu et al. [2020]. However, as the parameter count of these foundation models escalates, the conventional approach to fully fine-tuning becomes prohibitively expensive in various aspects.

To tackle this challenge, recent works Chen et al. [2024], Guo et al. [2020], He et al. [2021a], Hu et al. [2021] have focused on the concept of parameter-efficient fine-tuning (PEFT), aiming to minimize the number of adjustable parameters required while achieving optimal task performance. These works specifically explore methods to model the incremental update of pre-trained weights in a manner that is economical in terms of parameters, without necessitating changes to the model's architecture

^{*}Corrsponding author.

Figure 1: Difference between LoRA and FLoRA. LoRA employs low-rank matrix decomposition for each dimensional parameter space. However, for parameter space of convolution layer, the reshaping operation required by LoRA causes adjacent elements within the kernel to be separated in the reshaped matrix, disrupting the spatial locality inherent in the original convolutional space. Conversely, FLoRA asserts that the alternations of each dimensional parameter space has a low-rank core space with the consistent topological structure. This framework enables FLoRA to effectively preserve the structural integrity of the original parameter space, such as maintaining the spatial locality in convolutional operations.

Zaken et al. [2021], Guo et al. [2020], Hu et al. [2021]. Among these works, LoRA Hu et al. [2021] emerges as a pioneering effort, which proposes to adopt an additional term with a low-rank structure to the original weight. Specifically, the original weight matrix $\mathbf{W}_0 \in \mathbb{R}^{d_1 \times d_2}$ remains frozen, while a learnable low-rank $\Delta \mathbf{W}$ is added to \mathbf{W}_0 , with the form as

$$\mathbf{W}_0 \to \mathbf{W}_0 + \Delta \mathbf{W} = \mathbf{W}_0 + \mathbf{B}\mathbf{A}^{\mathsf{T}},\tag{1}$$

where $\mathbf{A} \in \mathbb{R}^{d_2 \times r}$ and $\mathbf{B} \in \mathbb{R}^{d_1 \times r}$ with $r \ll \{d_1, d_2\}$. Given that r is significantly smaller than the dimension of \mathbf{W}_0 , LoRA necessitates the updating of only a limited number of trainable parameters, while achieving comparable performances. Subsequent to LoRA, recent studies He et al. [2021a], Bershatsky et al. [2024], Zhang et al. [2022] endeavor to explore more efficient low-rank matrix decomposition methods concerning the matrix $\Delta \mathbf{W}$.

However, we have observed an intriguing phenomenon: a significant portion of existing works is narrowly focused on two-dimensional parameter spaces (i.e., linear layers), neglecting the existence of other dimensional spaces such as 2D convolution (4-dimension) layers, etc. But in practice, not all layers are linear across various models for downstream tasks. For example, ConvNeXt Liu et al. [2022] and Stable Diffusion Carreira and Zisserman [2017] are two models predominantly utilizing 2D convolutional layers. Alternatively, some approaches can be adapted for high-dimensional parameter spaces by directly adopting low-rank **matrix** decomposition. They transform alternations in high-dimensional spaces into two dimensions, while neglecting the structural complexities of the original spaces. For instance, as detailed in Sec. 3.1 and Fig. 1, LoRA Hu et al. [2021] compresses the changes in convolutions, which is a four-dimensional parameter space, into two dimensions. It subsequently applies low-rank matrix decomposition to the two-dimension space, , intending to represent the alterations of the original four-dimensional parameter space. Yet, as discussed in Sec. 3.2, this transformation fails to capture the inherent complexity and spatial locality specific to convolution operations. The result is a reshaped two-dimensional structure that compromises the integrity of the original parameter space, leading to a representation that does not fully encapsulate the convolutional alternation parameter space.

To this end, in this paper, we propose a low-rank **tensor** decomposition based method, FLoRA, represented as Fundamental LOw-Rank Adaptation. Positioned as a superior alternative to LoRAs, FLoRA, based on Tucker decomposition Tucker [1966], meets the ensuing three properties:

- It can identify a appropriate low-rank representation for the changes in various dimensional parameter spaces, without destructing the structural integrity of the original parameter spaces.
- It can maintain a consistent formulation across various dimensional parameter spaces.

• When applied to linear weights, with the same parameter budget, it requires a similar training time and resources to that of LoRAs, yet yield superior performance.

Specifically, since a much lower rank than the direct rank of parameter space is sufficient to represent the original space Aghajanyan et al. [2020], Li et al. [2018], FLoRA asserts that the alternations of each dimensional parameter space, whether 2D or 4D, have a corresponding core space. This core space is low-rank and retains the same spatial dimensions (i.e., 2D or 4D) as the original parameter space, suggesting that they share a consistent topological structure. FLoRA then models the alternations by using this core space combined with a series of weights to reconstruct alternations in the original parameter space. Thanks to the intrinsic properties in the structure of the core space, FLoRA efficiently maintains the structural integrity of the original parameter space. Extensive experiments are conducted with several pretrained models on computer vision, natural language processing and multi-modal tasks, which validates that regardless of the model, the kind of downstream task, or the dimensionality of the parameter space, FLoRA's performance surpasses that of LoRA and other existing methods.

The contributions of this paper are as follows:

- We propose a novel PEFT method, FLoRA. To the best of our knowledge, it is the first time that a PEFT method has been designed for different dimensional parameter spaces, aiming to preserve their topological structure while seeking low-rank representations.
- Extensive experiments on different tasks, include computer vision, natural language processing and multi-modal tasks, demonstrates that FLoRA significantly surpasses other baselines, validating the effectiveness of FLoRA.

2 Related Work

Methods for Parameter-Efficient Fine-tuning (PEFT) have been conceived to mitigate the substantial computational costs associated with the fine-tuning of large-scale models. This economization is realized by honing a comparatively minute fraction of the overall parameters, selected strategically for adaptation to a variety of downstream tasks. Current PEFT techniques can be divided into three distinct categories Liu et al. [2024b], Ding et al. [2023]: Adapter-based Houlsby et al. [2019], Chen et al. [2022], Luo et al. [2023], He et al. [2021a], Mahabadi et al. [2021], Karimi Mahabadi et al. [2021], prompt-based Lester et al. [2021], Razdaibiedina et al. [2023], Wang et al. [2023b], Shi and Lipani [2023], Fischer et al. [2021], Qiu et al. [2023], Renduchintala et al. [2023], Kopiczko et al. [2023], YEH et al. [2023], Zhang et al. [2022]. The first category of method integrates linear modules either sequentially or concurrently with the existing layer to enhance the performance, and the second class introduces additional soft tokens (prompts) to the initial input and concentrate exclusively on refining these trainable vectors. The last type, proposed by LoRA Hu et al. [2021], adopts low-rank matrix decomposition to model the change of the weight during fine-tuning, and are capable of merging with pre-trained weights.

However, as mentioned in the introduction, these methods only focuses on linear weight or destructing the structural integrity of high dimensional parameter spaces. To this end, in this paper we propose a novel PEFT method, aimed to address various dimensional parameter space.

3 Preliminaries

3.1 Low Rank Adaptation

LoRA Hu et al. [2021] models the incremental update of a pre-trained weight matrix $\mathbf{W}_0 \in \mathbb{R}^{d_1 \times d_2}$ by the product of two small matrices $\mathbf{A} \in \mathbb{R}^{d_2 \times r}$ and $\mathbf{B} \in \mathbb{R}^{d_1 \times r}$, where $r \ll \{d_1, d_2\}$. For $\mathbf{h} = \mathbf{W}_0 \mathbf{x}$, the modified forward pass is

$$\mathbf{h} = \mathbf{W}_0 \mathbf{x} + \Delta \mathbf{W} \mathbf{x} = \mathbf{W}_0 \mathbf{x} + \mathbf{B} \mathbf{A}^{\mathsf{T}} \mathbf{x}.$$
 (2)

Matrix A is initialized with a random Gaussian distribution, and B with zeros, setting the initial ΔW to zero for training. LoRA's application is straightforward to the linear layers, while for a convolution layer characterized by weights $W_c \in \mathbf{R}^{d_{in} \times d_{out} \times k \times k}$, with d_{in} / d_{out} denoting the dimension of

input / output respectively and k representing the kernel size, LoRA is adapted based on matrix decomposition:

$$\mathcal{W} = \mathcal{W}_c + \Delta \mathcal{W} = \mathcal{W}_c + Reshape(\mathbf{B}_c \mathbf{A}_c^{\mathsf{T}}, \mathcal{W}_c), \tag{3}$$

where $\mathbf{A}_c \in \mathbb{R}^{kd_{out} \times r}$ and $\mathbf{B}_c \in \mathbb{R}^{kd_{in} \times r}$. Here, $Reshape(\mathbf{B}_c \mathbf{A}_c^{\mathsf{T}}, \mathcal{W}_c)$ involves altering the dimensions of $\mathbf{B}_c \mathbf{A}_c^{\mathsf{T}}$ to match those of \mathcal{W}_c . It is obvious that LoRA unfolds the original 4-dimensional parameter space $\Delta \mathcal{W}$ into a 2-dimensional space, subsequently leveraging the low-rank approximation of this 2-dimensional space to represent the original 4-dimensional construct. As shown later, this low-rank matrix decomposition based method will destruct the structural integrity of the convolution layer.

3.2 Why Matrix Decomposition Breaks the Structural Integrity of the Convolution?

A high-dimension tensor can be decomposed based on low-rank matrix decomposition following Eq. (3). However, during the reshaping process, elements that were adjacent within the convolutional kernel may become scattered across various positions in the matrix. More specifically, elements that were localized within the convolutional kernel may now span multiple rows or columns of the reshaped matrix. This shift poses significant challenges in learning spatial correlations among elements positioned disparately. Therefore, such a transformation disrupts the principle of locality inherent in the original convolutional operation, where each output element is determined by a small region of the input.

3.3 Tucker Decomposition

Tucker decomposition Tucker [1966] is one of the well-studied algebraic tensor decomposition. Formally, given a tensor $\mathcal{X} \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$, where N is the order of the tensor (i.e., the number of dimensions or modes), Tucker decomposition represents \mathcal{X} as a product of a core tensor $\mathcal{G} \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_N}$ and a matrix along each mode n, $\mathbf{A}^{(n)} \in \mathbb{R}^{I_n \times J_n}$, where J_n can be considered as the dimension of the core tensor along mode n. The decomposition can be compactly written as:

$$\mathcal{X} = \mathcal{G} \times_1 \mathbf{A}^{(1)} \times_2 \mathbf{A}^{(2)} \times \dots \times_N \mathbf{A}^{(N)}, \tag{4}$$

where \times_n denotes the or mode-*n* product between a tensor and a matrix. The core tensor \mathcal{G} represents the interactions between different modes, and the matrices $\mathbf{A}^{(n)}$ are analogues to principal components within each respective mode. The selection of dimensions J_1, J_2, \ldots, J_N allows for a balance between desired approximation quality and computational efficiency, tailored to the specific requirements of the task at hand. Tucker decomposition decomposes any dimensional space into a core tensor and a set of matrices related to the dimensions, without altering the original structure. Specifically, these matrices only transform the representation of different dimensions, which means that as long as the core tensor accurately captures the relationships among these dimensions, the property of original parameter space can be preserved through this decomposition.

4 Method

In this section, we first introduce the formulation of FLoRA in an N-dimensional parameter space. Specifically, for a pre-trained weight $W_0 \in \mathbb{R}^{I_1 \times I_2 \times \cdots \times I_N}$ with N-dimension, we model its update ΔW as

$$\mathcal{W}_0 \to \mathcal{W}_0 + s * \Delta \mathcal{W} = \mathcal{W}_0 + s * \mathcal{G} \times_1 \mathbf{A}^{(1)} \times_2 \mathbf{A}^{(2)} \times \cdots \times_N \mathbf{A}^{(N)}$$
(5)

without loss of generality. Here $\mathcal{G} \in \mathbb{R}^{J_1 \times J_2 \times \cdots \times J_N}$ and $\mathbf{A}^{(n)} \in \mathbb{R}^{I_n \times J_n}$, where $J_n \ll I_n$. FLoRA considers the tensor \mathcal{G} as a low-rank core space with the consistent topological structure to the original parameter space, with $\mathbf{A}^{(n)}$ representing the weights associated with each dimension. We then scale $\Delta \mathcal{W}$ by *s* with *s* being a constant. In the subsequent subsections, we will detail its manifestations in convolution and linear layers.

4.1 FLoRA for Convolution Layer

Convolution operations in deep learning are characterized by a four-dimensional parameter space, encapsulated in a weight tensor $W_c \in \mathbf{R}^{d_{in} \times d_{out} \times k \times k}$, with d_{in} / d_{out} denoting the dimension of input / output respectively and k representing the kernel size. A pivotal property to consider within W_c is the spatial locality, which plays an essential role in the convolution layer's ability to compile

and process information across the input matrix. This process is facilitated by the kernel's spatial dimensions $(k \times k)$, which determines the scope of the input data scrutinized by each convolution operation. To preserve the attributes of the spatial locality and uphold the convolution parameter space's integrity, FLoRA models the update ΔW for a convolution layer as

$$\Delta \mathcal{W} = \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} \times_3 \mathbf{C} \times_4 \mathbf{D}, \tag{6}$$

where $\mathcal{G} \in \mathbb{R}^{r_1 \times r_2 \times r_3 \times r_3}$, $\mathbf{A} \in \mathbb{R}^{d_{in} \times r_1}$, $\mathbf{B} \in \mathbb{R}^{d_{out} \times r_2}$ and \mathbf{C} , $\mathbf{D} \in \mathbb{R}^{k \times r_3}$. r_1 , r_2 are ranks which are significantly smaller than $\{d_{in}, d_{out}\}$. r_3 is a rank smaller than the kernel size k of a convolution layer. Given that 3×3 convolution is a prevalent configuration in convolutional foundation models Woo et al. [2023], Rombach et al. [2022], Wang et al. [2023a], r_3 is consequently set to $\{1, 2\}$.

The core tensor \mathcal{G} in FLoRA can be viewed as a compressed convolution parameter space. In essence, it serves as a core space for convolution. This means that **in any convolution layer, there exists a convolution core**, and what FLoRA aims to do is to determine this convolution core for each convolution space and configure the corresponding weights **A**, **B**, **C** and **D** for reconstructing that space. Different to low-rank matrix decomposition based methods, FLoRA dose not need to alter the structure of the convolution. Alternatively, by learning the convolution core, FLoRA effectively preserves the convolution's property of spatial locality.

Furthermore, while preserving or potentially augmenting the representational power of the convolution process, FLoRA achieves a remarkable reduction in the number of trainable parameters in comparison to LoRAs. Assuming that the rank for both the input and output dimensions is uniform $(r_1 = r_2 = r)$, the parameter requirement for FLoRA is calculated as $O(r_3^2r^2 + r(d_{in} + d_{out}) + 2r_3k)$ parameters, while LoRAs necessitate training at least $O(rk(d_{in} + d_{out}))$ parameters. Given that typically $r, k \ll \{d_{in}, d_{out}\}$, therefore, FLoRA exhibits better parameter efficacy than LoRA as the number of the kernel increases.

4.2 FLoRA for Linear Layer

For a linear layer with weight $\mathbf{W}_0 \in \mathbb{R}^{d_1 \times d_2}$, FLoRA models the update $\Delta \mathbf{W}$ as

$$\Delta \mathbf{W} = \mathcal{G} \times_1 \mathbf{A} \times_2 \mathbf{B} = \mathbf{A} \mathbf{G} \mathbf{B}^\mathsf{T},\tag{7}$$

where $\mathbf{G} \in \mathbb{R}^{r_1 \times r_2}$, $\mathbf{A} \in \mathbb{R}^{d_1 \times r_1}$ and $\mathbf{B} \in \mathbb{R}^{d_2 \times r_2}$. Similar to that for convolution layer, the core matrix \mathbf{G} can be viewed as a core space for the 2-dimension parameter space, with \mathbf{A} and \mathbf{B} being the corresponding weights to reconstruct the alternations in linear space.

5 Experiment

5.1 Models and Datasets

We conduct comprehensive experiments across computer vision (CV), natural language processing (NLP) and multi-modal (MM) tasks.

Specifically, for CV tasks, we employ FLoRA to fine-tune the ConvNeXt-V2-L Woo et al. [2023], evaluating it on MS COCO Lin et al. [2014] by using Mask R-CNN He et al. [2017] implemented in

Figure 2: The normalized performance improvement of FLoRA over other baselines

MMDetection Chen et al. [2019], and on remote sensing image datasets DOTA Xia et al. [2018] with Oriented R-CNN Xie et al. [2021] based on MMRotate Zhou et al. [2022], and on the ADE20K Zhou et al. [2017] dataset thanks to UperNet Xiao et al. [2018] integrated in MMSegmentation Contributors [2020]. We also employ FLoRA to fine-tune large-scale vision foundation model, i.e. InternViT-6B Chen et al. [2023], on ADE20K datasets. Detailed hyper-parameter settings can be find in Appendix.

For NLP tasks, we evaluate the DeBERTaV3-base He et al. [2021b] with FLoRA on the General Language Understanding Evaluation (GLUE) Wang et al. [2018] benchmark, which includes two single-sentence classification, three similarity and paraphrase and four natural language inference datasets. More details on GLUE dataset can be found in the Appendix.

For multi-modal tasks, we employ FLoRA to fine-tune LLaVA-1.5-7B Liu et al. [2024a], which is composed of a language model, Vicuna-1.5-7B Peng et al. [2023] and a vision encoder, CLIP ViT-L/336px Radford et al. [2021], on visual instruction tuning tasks, which include seven vision-language benchmarks: VQA^{v^2} Goyal et al. [2017], GQA Hudson and Manning [2019], VisWiz Gurari et al. [2018], SQA Lu et al. [2022], VQA^T Singh et al. [2019], POPE Li et al. [2023], and MMBench Liu et al. [2023].

Moreover, we have also fine-tune Stable Diffusion Rombach et al. [2022] with FLoRA in Appendix.

5.2 Baselines

We compare FLoRA with several state-of-the-art methods: fully fine-tuning, BitFit Zaken et al. [2021], HAdapter Houlsby et al. [2019], PAdapter Pfeiffer et al. [2020], AdaLoRA Zhang et al. [2022], the most representative low-rank method, LoRA Hu et al. [2021], and the state-of-the-art low-rank adaption method, DoRA Liu et al. [2024b]. Specifically, HAdapter is strategically placed between the self-attention module and the FFN module, and it includes a subsequent residual connection. Conversely, PAdapter introduces a more streamlined design, implementing adapters exclusively after the FFN modules and LayerNorm modules. Furthermore, following Zhang et al. [2022], we apply AdaLoRA, LoRA and DoRA to all weight matrices or tensors. For more details on the baselines, please refer to their original papers.

5.3 Implementation Details

We compare FLoRA with other PEFT methods under different parameter budgets. The hidden dimension of Adapters is chosen from {8, 16, 32, 64}, the budget of AdaLoRA is chosen from {144, 288,567} and the rank r of LoRA and DoRA is selected from {2, 4, 8, 16, 32}. Other hyperparameters are initialized according to their original papers. Furthermore, we simply set $r_1 = r_2$ for FLoRA. The scale s is chosen from {0.04, 0.4, 4} for different foundation models. We use publicly available PyTorch Paszke et al. [2019] implementation to execute all the baseline comparisons, and all the experiments are conducted on NVIDIA A100 GPUs. For NLP tasks, the mean of 5 runs using various random seeds are reported for all the experiments, and all gains have passed the pairwise t-test with a significance of 0.05. The tensor \mathcal{G} is initialized as zero, while other weight matrices are initialized as random Gaussian. For more training details, please refer to the Appendix.

5.4 Main Results

We compare FLoRA with other baselines under different parameter budgets. Specifically, ConvNeXt-V2-L is based on convolutions, and other large foundation models are dominantly based on linear layers. We evaluate FLoRA's effectiveness on high-dimension space for the CV tasks, and on linear parameter space for CV and NLP tasks. The results are shown in Tables. 1-3 and Table in Appendix, and the normalized performance are illustrated in Fig. 2.

For CV tasks, FLoRA employed on ConvNeXt-V2-L achieves superior performances compared to other baselines. On average, FLoRA outperforms LoRA and DoRA by at least **15%** under different parameter budgets. With nearly **80%** reduction in parameter budget, FLoRA (12.77M) still significantly outperforms LoRA (51.78M), DoRA (51.95M), validating that FLoRA successfully preserves the structural integrity of convolutions. Specifically, FLoRA achieves comparable or even superior performance to fully fine-tuning, while others lag far behind. Additionally, we observe that on tasks with a large domain gap from the pre-training data, e.g. remote sensing images (DOTA), LoRA and DoRA performs significantly worse, while FLoRA maintains consistent superiority. This further validates the robustness of FLoRA, even when facing tasks with large domain gaps. Moreover, when FLoRA is employed to fine-tune InternViT-6B, FLoRA consistently outperforms the baseline across various parameter budgets. Remarkably, by fine-tuning only **0.66%** of the parameters, FLoRA achieves even better performance than fully fine-tuning.

For NLP tasks, FLoRA achieves better or on par performance compared with existing approaches on all datasets under all different parameter budgets. Specifically, under extreme low parameter budget, FLoRA performs better even than the baselines with higher parameter counts. For example, with **0.3M** parameters, FLoRA's performances on SST-2, QNLI, RTE, MRPC and STS-B are all better than baselines with larger parameter budgets.

For multi-modal tasks, FLoRA also achieves SOTA performances compared with baselines. Therefore, at this point, we can conclude that overall, FLoRA achieves remarkable performances across various tasks, model backbones, and dimensions of parameter spaces.

6 Further Analysis

In this section, we explore the properties of FLoRA when applied to downstream tasks and in comparison with other baselines like LoRA. We carry out a series of empirical studies to address the following questions: 1) Is the core space truly low-rank? 2) If so, why is FLoRA's low-rank representation better than other methods like LoRA? 3) Does FLoRA require acceptable training

costs compared to other methods? 4) Is FLoRA sensitive to the scaling factor? The insights gained from these questions will illuminate the efficacy of FLoRA and guide future research.

Figure 3: Fine-tuning with FLoRA under different rank (parameter budgets).

6.1 Is the Core Space Truly Low-rank?

We present the performance of FLoRA under different rank (i.e., parameter budgets), tested on ConvNeXt-V2-L and DeBERTaV3-base. The results are illustrated in Fig. 3. It is evident that FLoRA's performance with a low rank is comparable to, or even exceeds, that of a higher rank. This finding aligns with observations in Hu et al. [2021]. It indicates that there indeed exists a core space in different dimensional spaces, and the rank of the core space is relatively small. When the rank set is smaller than the rank of the core space, the performance of the model is not optimal. Conversely, when it exceeds this rank, the core space is completely covered, which introduces some meaningless redundancy and noise. Additionally, we observe that for the convolutional parameter space, the rank of its core space is much larger, for the convolutional space has a more complex topological structure, necessitating a larger rank to adequately describe it.

6.2 Why is FLoRA's Low-rank Representation Better than Other Methods?

Although methods like FLoRA and LoRA can represent changes in the original parameter space using low-rank representations, FLoRA performs better, indicating that its low-rank representation is superior to other forms of low-rank representations. We will explain the reasons as follows.

6.2.1 Theoretical Analysis

In linear parameter spaces, the changes modeled by methods in the LoRA derivatives, can also be simply considered as **AGB** with **G** being a diagonal matrix. However, FLoRA does not impose any constraints on **G**, which offers several advantages: firstly, it broadens the range of parameter adjustments and enhances the flexibility of parameter learning. Secondly, FLoRA removes the strong orthogonality constraint on **G**. Since orthogonality is not a characteristic of all downstream tasks, enforcing orthogonal constraints during the learning process could potentially degrade performance, as shown in Tables 1-3. Lastly, since **G** is initialized to zero in FLoRA, under certain conditions, **G** may also learn to exhibit orthogonal properties. This indicates that the low-rank representations of methods like LoRA are a special case of FLORA, which possesses a more robust low-rank representation capability, thereby yielding better performance.

For high-dimensional parameter spaces, as previously discussed, other methods compromise the structural integrity of the original parameter spaces. In contrast, FLoRA preserves their topological structure, leading to superior performance outcomes.

6.2.2 Empirical Analysis

To further substantiate the theoretical analysis on FLoRA's superiority, we record the average of the Frobenius norm of $\Delta \mathbf{W}$ and the *feature amplification factor* $\frac{\|\Delta \mathbf{W}\|_F}{\|\mathbf{U}^{\mathsf{T}}\mathbf{W}\mathbf{V}^{\mathsf{T}}\|_F}$ Hu et al. [2021] of all the layers in DeBERTaV3-base on CoLA during training. Here U and V being the left- and right-singular matrices of the SVD decomposition of $\Delta \mathbf{W}$. The feature amplification factor measures how much of task-specific information are amplified by $\Delta \mathbf{W}$.

Figure 4: Average of the Frobenius norm of ΔW and the feature amplification factor during training.

The results, illustrated in Fig. 4, show that LoRA and DoRA can amplify task-specific features more than FLoRA in the early stages. As discussed in Sec. 6.2.1, these two methods exhibit strong orthogonality, resulting in a distinct directional learning pattern at the beginning, which contributes to their larger initial values. However, strong orthogonality may not always be suitable for downstream tasks, and since downstream datasets may possess various properties, their amplification factors upon convergence are smaller than that of FLORA.

Additionally, we found the trend of the Frobenius norm closely aligns with the feature amplification factor, surprisingly. This might indicate that larger ΔW values can accommodate more task-specific information, thereby more effectively amplifying the task-specific information in the frozen weights. We also observed that, initially, the Frobenius norms of ΔW for LoRA and DoRA are also larger than that of FLoRA, for they can quickly capture the orthogonal information if the downstream datasets. However, upon convergence, they are both smaller than FLoRA's, suggesting that FLoRA can contain more kinds of properties for task-specific information.

6.3 Does FLoRA Require Acceptable Training Costs Compared to Other Methods?

We assess the training costs under various configurations. All training hyper-parameters, such as batch size and epochs, are kept consistent, with the results presented in Table 4. Clearly, FLoRA is more efficient in terms of training time and memory footprint compared with SOTA method DoRA, which require significantly more time and GPU memories.

ConvNeXt-V2-L							DeBERTaV3-base							
Method _{# D}	# Donoma	COCO		ADE20K		Method	# Donoma	MNLI		SST-2		STS-B		
	# rarains	Time	GPU	Time	GPU	# Faranis	Time	GPU	Time	GPU	Time	GPU

Table 4: Training time (minutes/epoch) and GPU usage (GB) of FLoRA.

6.4 Is FLoRA Sensitive to the Scaling Factor?

We report the sensitivity w.r.t. the scale s on ConvNeXt-V2-L and DeBERTaV3-base, and the results are shown in Fig. 5. It is obvious that the performance of FLoRA is quite stable with the scale changing in a reasonable range, which is a desirable property in practice.

7 Conclusion and Limitation

In this paper, we propose a generalized low-rank tensor decomposition based PEFT method, FLoRA, aiming for N-dimension parameter space. FLoRA asserts that the alternations in each dimensional parameter space contain a low-rank core space structurally consistent to the original space. It models updates using this core space alongside corresponding weights to reconstruct the original alternation space. By doing so, FLoRA effectively preserves the structural integrity of the original N-dimensional parameter space while decomposing it through low-rank tensor decomposition. Extensive

Figure 5: Sensitivity analysis of FLoRA w.r.t. scale s.

experiments on computer vision, natural language processing and multi-modal domains substantiate the effectiveness of FLoRA.

There still exists some limitations for FLoRA. For a specific backbone, FLoRA could achieve stable superior performance on different datasets when the scaling factor *s* changing within a wide range. While for different backbones such as ConvNeXt-V2-L, InternViT-6B and DeBERTaV3-base, it still needs different scales. Understanding the role of scale in different models and designing a unified scale is a topic worthy of further investigation.
