Abstract

Optimizing multiple objectives simultaneously is an important task for recommendation platforms to improve their performance. However, this task is particularly challenging since the relationships between different objectives are heterogeneous across different consumers and dynamically fluctuating according to different contexts. Especially in those cases when objectives become conflicting with each other, the result of recommendations will form a pareto-frontier, where the improvements of any objective comes at the cost of a performance decrease of another objective. Existing multi-objective recommender systems do not systematically consider such dynamic relationships; instead, they balance between these objectives in a static and uniform manner, resulting in only suboptimal multi-objective recommendation performance. In this paper, we propose a *Deep Pareto Reinforcement Learning* (DeepPRL) approach, where we (1) comprehensively model the complex relationships between multiple objectives in recommendations; (2) effectively capture personalized and contextual consumer preference for each objective to provide better recommendations; (3) optimize both the short-term and the long-

term performance of multi-objective recommendations. As a result, our method achieves significant pareto-dominance over the state-of-the-art baselines in the offline experiments. Furthermore, we conducted a controlled experiment at the video streaming platform of Alibaba, where our method simultaneously improved three conflicting business objectives over the latest production system significantly, demonstrating its tangible economic impact in practice.

1 Introduction

Recommender systems have experienced widespread adoption since they provide numerous benefits to consumers and platforms (Hosanagar et al. 2014; Ribeiro et al. 2014, Panniello et al. 2016). Existing literature (Adomavicius & Kwon 2007; Adomavicius et al. 2010) demonstrates that it is beneficial to optimize multiple objectives simultaneously to improve the business performance across multiple fronts, such as maximizing revenues from ads *and* improving click-through rates from consumers (Kamakura et al. 1996; Roijers et al. 2013). To this end, multi-objective recommender systems have been successfully introduced in major companies, such as YouTube (Ma et al. 2018) and Alibaba (Ma et al. 2018b).

One critical challenge of multi-objective recommender systems is associated with the pareto frontier issue, where improving the performance of one objective comes at the expense of another one, especially when they are conflicting with each other (Ribeiro et al. 2014). For example, there is a well-known conflict between the objectives of Video View (VV, the average number of videos watched in each session) and Dwell Time (DT, the average time spent in each session) in video streaming platforms (Cheng et al. 2013): on one hand, focusing on the VV

metric may produce short-length, clickbait video recommendations that reduce the DT metric. On the other hand, if the focus is on the DT metric, the platform tends to recommend long-length videos, which might not fit well with consumer satisfaction and lead to a decrease in VV. Since both objectives all have significant impact on consumer experiences (Sahoo et al. 2012), it is therefore crucial to optimize the pareto frontier to improve multi-objective recommendations.

To this end, a series of multi-objective recommendation models have been proposed to accomplish this task (Ribeiro et al. 2014). However, the research gap in the literature lies in that they do not systematically model the heterogeneous and dynamic relationships between objectives. Instead, static objective weights have been predominately used in existing models (Zheng & Wang 2022), resulting in only sub-optimal performance. This is the case, since the behavioral marketing theory (Häubl & Trifts 2000; Häubl et al. 2010) reveals that consumers' decision-making is contingent on the intrinsic consumer nature and the decision context, rather than being invariant. Therefore, their preferences of different recommendation objectives fluctuate accordingly, resulting in heterogeneous and dynamically evolving relationships between these objectives. For example, some consumers prefer to stay within their own comfort zones to receive familiar products, while others are willing to enjoy relevant content and explore novel content at the same time. In the former case, relevance and novelty works exclusively in a conflicting manner, while they are complementary to each other in the latter case when they jointly produce recommendations to best fit consumers' needs. In another example, a certain consumer might be more willing to listen to rock-and-roll music on a weekday morning that

would energize him/her for the day, versus listening to relaxing music on weekend afternoons.

To address this research gap, we propose a *Deep Pareto Reinforcement Learning (DeepPRL)* model in this paper, which continuously calibrates the relationship between objectives based on personalized and contextualized information, rather than modeling this relationship in a static and uniform manner, as was previously done in the literature. It consists of the following two components that we propose in the paper as a part of the DeepPRL model: (1) the “Mixture of HyperNetwork” module, in which we build multiple deep-learning-based hypernetworks (Navon et al. 2021), one for each objective, to capture the latent information related to each objective, so that we can select suitable products to improve the pareto frontier with respect to that objective. The outputs are aggregated through a mixture attention network that captures the intrinsic relationships between different objectives and jointly predict their values. (2) the “Deep Contextual Reinforcement Learning” module, in which we dynamically adjust the weights of multiple objectives based on the personalized and contextualized consumer preferences towards each objective, leading to most suitable recommendations and optimized performance results along multiple fronts of the pareto frontier. It also enables us to model the impact of current consumer actions on future consumer preferences, since we take into account the future reward in the reinforcement learning process (Afsar et al. 2022). Integration of these two modules into the unified DeepPRL model provides the following advantages. First, it automatically balances different objectives based on contextualized and evolving consumer preferences. Second, it improves both the short-term and the long-term performance, which

further enhances practicality of multi-objective recommender systems, since many existing approaches suffer degradation of performance in the long run (Devooght & Bersini 2017). Third, it also provides nice theoretical properties, which we will explain further in Section 4.

The advantages of our proposed method are further empirically demonstrated through extensive offline experiments in three different applications of Alibaba-Youku, Yelp, and Spotify, where our method significantly improves performance *across all considered objectives*, as compared to the state-of-the-art multi-objective recommender systems and dominates their pareto frontiers, regardless of the specific datasets or the heterogeneous relationships between the objectives. In addition, to illustrate practical impact of our framework, we conducted a large-scale online experiment on the video streaming platform of Alibaba, where our proposed method *simultaneously* improved the performance of the three conflicting objectives of Click-Through Rate, Video View, and Dwell Time by 2%, 5%, and 7% respectively, as compared to the latest production system in the company, thus producing tangible economic benefits for the platform.

In this paper, we make the following research contributions. First, we provide empirical evidence to illustrate the importance of modeling personalized and contextualized information, and adjusting the weight of each objective accordingly, in order to improve multi-objective recommendation performance. Second, we propose a deep pareto reinforcement learning method that not only effectively achieves this goal, but also provides other important modeling benefits, such as optimizing long-term recommendation performance. Third, we present theoretical properties of our method contributing to its superior performance. We also empirically

demonstrate its advantages vis-à-vis the state-of-the-art baselines through extensive offline experiments, where it achieves significant performance improvements across multiple objectives and experimental settings, and dominates pareto-frontiers of these methods. Finally, we illustrate its practical impact through an online controlled experiment, where it significantly outperforms the latest production system in the company across three conflicting objectives simultaneously.

2 Related Work

2.1 Multi-Objective Recommender System

As illustrated in the literature (Sahoo et al. 2012; Ribeiro et al. 2014), it is beneficial to optimize multiple objectives simultaneously in recommendations, as opposed to only one objective (Adomavicius & Tuzhilin 2005). This finding is further justified in (Bauman & Tuzhilin 2022) and (Panniello et al. 2016), where researchers demonstrated that consumers actively pursue multiple objectives to improve their experiences across different dimensions, thus making multi-objective recommendations preferable (Sahoo et al. 2012; Zimmermann et al. 2018; Dzyabura & Hauser 2019). The economic benefits of providing multi-objective recommendations have also been discussed in the IS and marketing literature, where various aspects of such recommendations, including quality, taste-matching, diversity, and transparency have been explored (Xu et al. 2014; Shi & Raghu 2020; Yin et al. 2022).

To this end, a series of multi-objective recommender system methods have been proposed in the computer science literature, which can be classified into two groups (Zheng & Wang 2022). The first group utilizes a series of feature-based statistical learning methods, such as cross-stitch network (Misra et al. 2016), relational network (Zhao et al. 2019), and structural models

(Panniello et al. 2008) to predict jointly the objective values of the candidate product (Adomavicius et al. 2010; Rodriguez et al. 2012). The second group of methods constructs deep-learning-based multi-objective recommender systems, including Shared-Bottom (Ruder 2017), Multi-Gate Mixture-of-Expert (MMOE) (Ma et al. 2018), and Mixture of Sequential Experts (MoSE) (Qin et al. 2020), and is shown to be very effective in industrial practices. These models operate by first building a series of separate neural networks, each predicting the values of one specific objective based on the consumer and product features, and then aggregating these predicted objective values through a set of fixed weights to produce multi-objective recommendations. As a result, they manage to facilitate accurate joint predictions of multiple objectives and achieve strong performance.

Despite their usefulness, there are still a few fundamental problems associated with existing multi-objective recommender systems. First, they do not consider heterogeneous and dynamically evolving relationships between different objectives, which is a crucial factor in providing effective multi-objective recommendations, as is illustrated in the next section. Second, these methods do not systematically model the personalized and contextualized consumer preference towards different objectives, which plays an important role in multi-objective recommendations. Third, these methods do not obtain any theoretical properties related to the performance level that they will be able to achieve. To address these challenges, we propose a novel *Deep Pareto Reinforcement Learning (DeepPRL)* method in this paper to model the evolving relationships of different objectives based on dynamic information.

2.2 Personalized and Contextualized Consumer Preference in Recommendations

Personalization technique enables marketers to reach their potential customers in an effective manner (Ho & Lim 2018; Zhang et al. 2019) and produce customized experiences based on individual preferences (Thirumalai & Sinha 2013, Tuzhilin 2009), resulting in important competitive advantages (Johar et al. 2014). Therefore, it is widely adopted in recommender systems to identify suitable content (Adomavicius & Tuzhilin 2005), improve customer loyalty towards retailers (Tongxiao et al. 2011), post-consumption customer experience (Adomavicius et al. 2021) and advertising effectiveness (Bleier & Eisenbeiss 2015).

Another important technique in recommendations is contextualization (Gorgoglione et al. 2006; Bauman & Tuzhilin 2022), which captures the evolution of consumer preference affected by contextual factors, such as prior activities, time, and location (Palmisano et al. 2008; Unger et al. 2016). As shown in the literature (Panniello et al. 2016), contextualization significantly improves the accuracy and diversity of recommendations, which in turn improves trust and ultimately business performance, such as sales.

Therefore, numerous personalization methods, such as Collaborative Filtering (Konstan et al. 1997), Neural Collaborative Filtering (He et al. 2017), and Deep Interest Network (Zhou et al. 2018), and contextualization methods, such as Matrix Factorization (Koren et al. 2009), Hierarchical Linear Models (Umyarov & Tuzhilin 2009), and BERT4Rec (Sun et al. 2019), have been proposed in the literature. However, the research gap lies in that these models primarily focus on one single objective (such as Click-Through Rate), and the extension to a multi-objective recommendation scenario is usually not trivial. Therefore, we propose a Deep Pareto

Reinforcement Learning method in this paper that effectively models personalized, contextualized, and dynamically evolving consumer preference across multiple objectives, and show that it produces effective multi-objective recommendation performance results.

3 Preliminaries and Model-Free Evidence

3.1 Problem Formulation

In this section, we will present the model-free evidence to demonstrate the importance of personalized and contextualized information in modeling the relationships between different objectives. Before doing so, we first formally specify the multi-objective recommendation task.

We denote recommendation objectives as $\{y_1, y_2 \dots, y_n\}$, where n is the number of objectives and each y_i represents a particular objective of interest, such as novelty, diversity, consumer satisfaction, and so on. In many cases, however, the values of these objectives are not available prior to the recommendation. For example, click-through rate and watching time of a video can only be obtained based on consumer response after the video is recommended. Therefore, *a priori*, we need to predict their values $\{\widetilde{y}_1, \widetilde{y}_2 \dots, \widetilde{y}_n\}$ based on consumer and product information. Recommendations will then be produced by selecting those products with the highest utility values $\sum_k \alpha_k \widetilde{y}_k$, where each α_k represents the weight of objective y_k . Therefore, multi-objective recommendations rely on solving the following two-stage optimization problem:

$$(1) \min \sum_k |\widetilde{y}_k - y_k| \quad (\text{Stage 1: Minimizing the Prediction Error of Each Objective})$$

$$(2) \max \sum_k \alpha_k \widetilde{y}_k \quad (\text{Stage 2: Identifying the Optimal Weight of Each Objective})$$

This optimization is particularly challenging since it is an NP-hard problem (Xiao et al. 2017).

To make things worse, existing multi-objective recommender systems focus predominately on the first part of optimization to produce the objective prediction \widehat{y}_k , while identifying the optimal weights has been oversimplified in the sense that α_k is usually selected as a fixed value across different consumers and different recommendation contexts in these models (Ruder 2017; Ma et al. 2018; Qin et al. 2020), resulting in suboptimal performance. In the rest of this section, we will explain that both optimization tasks are heavily influenced by personalized and contextual information in recommendations, and motivate the design of our proposed DeepPRL model.

3.2 Motivating Example – Personalization & Contextualization

To better illustrate the idea, we will present a motivating example based on a consumer interaction record dataset collected from the production system at the video streaming platform of Alibaba, the same platform that we conducted the online experiment in Section 6. In total, this dataset contains the video-watching history of 516,201 consumers over one week from 07/29/2019 to 08/04/2019, resulting in 26,959,538 video-watching records. Video recommendations are generated using the latest production system in the company that simultaneously optimizes a wide range of objectives, including the Video View (VV) and Dwell Time (DT), which have been introduced in Section 1. Each objective (VV or DT) measures the quality of a certain consumer-video interaction, i.e., whether the consumer clicked on the recommended video or how much time the consumer spent on the recommended video. As we explained before, these two objectives in general are conflicting with each other. However, the level of negative correlations between them can fluctuate dramatically with respect to different

consumers and recommendation contexts, as shown below.

Evidence of Personalization. We compute the Pearson Correlation between the VV and DT objectives individually based on the videos each consumer has watched in our records and present the histogram in Figure 1, where the x-axis shows the correlation coefficients, and the y-axis represents the kernel density. We can observe from the figure that the relationships between them are highly heterogeneous across different consumers: although the average correlation level is -0.663, 29% of consumers have a correlation below -0.7 in their watching records, and 47% of consumers have a correlation above -0.5. Since there are significant variations of objective relationships across different consumers, it is crucial to capture the *personalized* information, such as demographics, personalities, and characteristics of consumers, to model their heterogeneous preferences towards different objectives in recommendations.

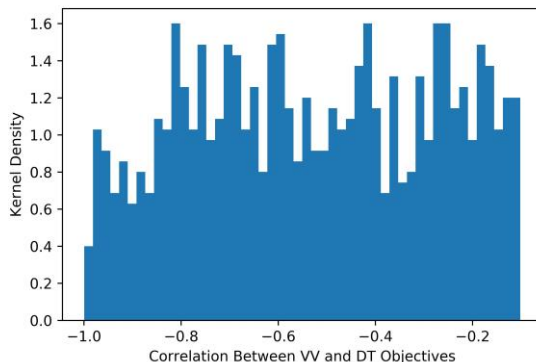

Figure 1: Visualization of Correlations Between VV and DT across Different Consumers

Evidence of Contextualization. Context is defined in the recommender system literature as “any additional information besides users and items that is relevant to recommendations” (Adomavicius et al. 2021). We consider the contextual information of the date and hour of video watching in our example, and compute the Pearson Correlation between the VV and DT

objectives across different times in our dataset. We similarly present the average correlation levels in Figure 2, where we plot the correlation coefficients on the y-axis across different times. We observe in Figure 2 how the relationship between these two objectives fluctuates significantly across different time periods, thus further demonstrating the importance of properly modeling contextual information, such as time, in our multi-objective recommendation task.

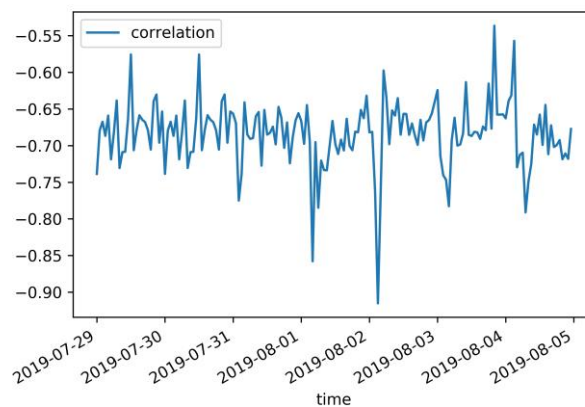

Figure 2: Visualization of Correlations Between VV and DT across the Context of Time

3.3 Optimization of the Pareto Frontier

Building on the empirical evidence from Section 3.2, in this section we present a toy example to show that incorporating personalized and contextualized information should significantly improve the pareto frontier of multi-objective recommendations. Before we do that, we will first introduce the preliminaries.

In multi-objective optimization, the optimal pareto frontier, or the pareto optimality, refers the set of all pareto efficient solutions, where there are no ways left to make one objective better-off, unless we are willing to make some other objectives worse-off (Emmerich & Deutz 2018). To achieve such performance level, multi-task learning method is commonly adopted (Ruder 2017),

where we simultaneously solve several individual learning tasks (one for each objective) while sharing information across different tasks. The final solutions are obtained through Linear Scalarization (LS) (Zhang & Yang 2021), in which each objective’s weight is chosen apriori in a fixed manner. To capture the evolving relationships between different learning tasks, some recent attempts have been made in the literature, including gradient magnitude (Chen et al., 2018), attention (Liu et al. 2019), task uncertainty (Kendall et al. 2018), and implicit differentiation (Navon et al. 2020) approaches. However, these models do not systematically model the trade-off between different objectives and the personalized and contextualized information, and as a result, achieve only suboptimal performance that is significantly worse than the pareto optimal.

To better illustrate the idea, we consider the following toy example, where we provide multi-objective recommendations for two objectives o_1 and o_2 , which are conflicting with each other but are both beneficial to the consumer experience. Following existing practices (Sun et al. 2019b), we simulate the perceived value of objective 1 & 2 for user u and item i using the discrete choice model as:

$$o_{u,i,1} = L[r_i + \eta_{u,i}] \quad o_{u,i,2} = 1 - c_{u,i} \times o_{u,i,1}$$

Where $r_i \sim N(0.5, 1)$ captures the features of item i relevant to objective 1, $c_{u,i}$ represents the relationship between two objectives that is associated with personalized and contextual factors that are uniformly distributed, $L[.]$ is the logit model, and $\eta_{u,i} \sim N(0, 0.1)$ is the error term. We simulate the records for 100 users and 100 items, resulting in 10,000 records in total, and then provide recommendations using two versions of the Shared-Bottom model (Ruder 2017), with

and without knowing $c_{u,i}$, and compare their performance with the theoretical pareto optimality that we can possibly achieve from this dataset. As we show in Figure 3, by taking into account the tradeoff between the two objectives, we will be able to significantly improve the pareto frontier of recommendations, and take it closer to the pareto optimality.

Motivated by this example, in this paper we propose a novel method to capture the tradeoff between different objectives in order to approach the optimal pareto frontier in multi-objective recommendations. Our method is built upon a state-of-the-art multi-task learning method HyperNetwork (Ma et al. 2020; Lin et al. 2020; Hoang et al. 2023). We enhance the HyperNetwork through an attention mechanism and connect it to the reinforcement learning technique, which is described in the next section. By doing so, we will empirically outperform existing solutions in the literature, as well as achieve nice theoretical properties.

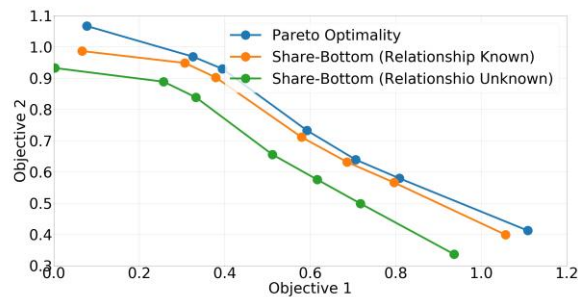

Figure 3: Simulation Example for Illustrating the Importance of Personalized & Contextualized Information

3.4 Reinforcement Learning

Examples and evidence presented in Sections 3.2 and 3.3 motivate the importance of modeling personalized and contextualized information in multi-objective recommendations. To achieve this goal, we select the reinforcement learning method (RL) (Mnih et al. 2015; Sutton & Barto 2018) in this paper since it is especially useful for capturing such information and updating

recommendations accordingly in real-time (Zheng et al. 2018). For example, (Liebman et al. 2019) presents a reinforcement learning framework for adapting to a listener’s current song preferences during each listening session. In addition, RL can also optimize the long-term multi-objective recommendation performance, which is crucial for industrial platforms to maintain competitiveness (Zou et al. 2019; Chen et al. 2019; Afsar et al. 2022) since many of them suffer from the degradation of recommendation performance in the long run.

Note that the RL problem addressed in this paper is significantly different from those studied in the literature, as we aim to improve optimize *multiple* dimensions of recommendations, rather than for only one objective. Following the RL terminology, we formulate our task through the following components:

- **State s** , which represents the personalized information of the consumer related to the current recommendation, based on which we determine the optimal action a accordingly.
- **Action a** , which represents a set of objective weights $a = \{\alpha_1, \alpha_2 \dots, \alpha_n\}$ determined by s that will to the objectives $\{y_1, y_2 \dots, y_n\}$.
- **Context C** , which is a vector $\vec{C} = \{c_1, c_2 \dots, c_n\}$ representing relevant contextual information that affects the selection of optimal actions in recommendations.
- **Reward R** , which represents the benefit of taking specific action a , given the state s and the context c in the current recommendation stage.

The goal of the RL method in our case is to select the optimal action a based on a given state s and context c in order to maximize reward r . To achieve this goal, we propose a *Deep Pareto*

Reinforcement Learning (DeepPRL) model that *simultaneously* achieves significant performance improvements over the state-of-the-art methods across multiple objectives. We will present the details of this model in the next section.

4 Deep Pareto Reinforcement Learning Model

4.1 Overview of Our Proposed Model

We will first present the overall schema of our DeepPRL model, which is shown in Figure 4, before introducing its details. It takes product features, consumer behaviors, and contextual information (shown in blue in Figure 4) as inputs, and produces the output of multi-objective recommendations (shown at the top in Figure 4). To do this, we first feed the product features and consumer behaviors into the embedding layer (as shown at the bottom) to generate the product embeddings and the consumer state representations. Then, these latent embeddings are used in our proposed “Mixture of Hypernetwork” module to predict the objective values $\{\widetilde{y}_1, \widetilde{y}_2 \dots, \widetilde{y}_n\}$. A hypernetwork (Navon et al. 2021) is a special type of a neural network that contains two separate networks: one network produces the prediction results based on the inputs, and the other network generates the weights and parameters of the first network. In our module, we construct n hypernetworks, one for each particular objective y_i to capture the objective-specific information and predict their values \widetilde{y}_i for each candidate product based on their input features. The predicted objective values are further calibrated through a mixture layer on top of these hypernetworks to capture the interactions between different objectives and aggregate their outputs. The details of this module will be discussed in Section 4.2.

Additionally, we also feed the consumer state representations and the context information

into Module 2 “Deep Contextual Reinforcement Learning”, as shown in Figure 4, and produce the set of objective weights $\{\alpha_1, \alpha_2 \dots, \alpha_n\}$ corresponding to the predicted objective values $\{\widetilde{y}_1, \widetilde{y}_2 \dots, \widetilde{y}_n\}$ generated in Module 1. It incorporates the context information to determine the optimal recommendation, which constitutes another contribution of this paper. We will describe the specifics of Module 2 in Section 4.3. In the final layer of Figure 4, we construct the aggregated utility function based on the outputs of Modules 1 and 2 as $\sum_k \alpha_k \widetilde{y}_k$, and then provide multi-objective recommendations by selecting those products with the highest utility values. We will now explain the details of our proposed method (as diagrammed in Figure 4).

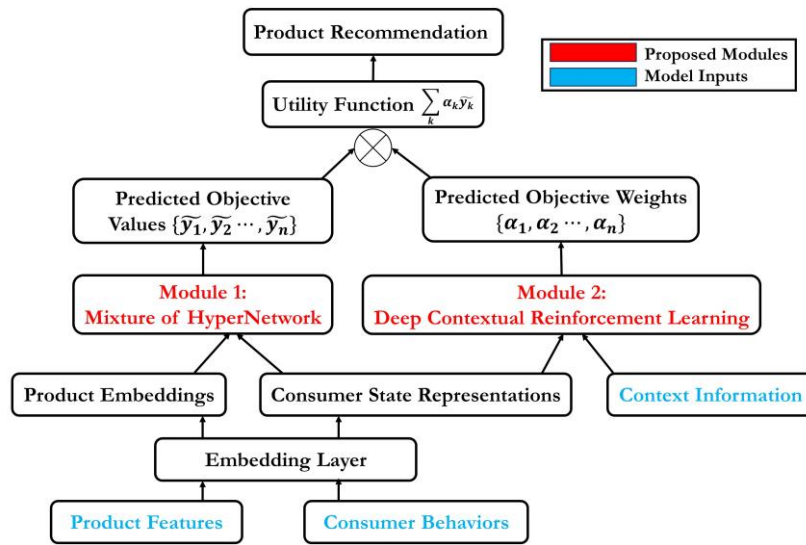

Figure 4: Overview of Our Deep Pareto Reinforcement Learning Model

4.2 Mixture of HyperNetwork

The first module in our proposed method (Module 1 in Figure 4), the “Mixture of Hypernetwork,” is designed to address the challenge described in Sections 2 and 3, where dynamic relationships between different objectives has not been properly modeled in the prior literature, resulting in suboptimal performance that does not reach the pareto optimal. Our

method addresses this problem by predicting the objective values with the HyperNetwork method (Ha et al. 2016), which operates by using one neural network to generate the weights for another neural network. An important property of the HyperNetwork is that it can be viewed as relaxed form of weight-sharing across different hidden layers; as a result, it is particularly suitable for modeling the tradeoff among multiple learning tasks and provides important theoretical benefits in mathematics, thus motivating the design choice in our model.

Figure 5: Overview of the Mixture of HyperNetwork Module

To this end, we construct a series of HyperNetworks, one for each recommendation objective, to capture the objective-specific information from the inputs of product features and consumer behaviors, both of which are modeled as embeddings in the latent space to capture the hidden and heterogeneous preference information. The outputs of HyperNetworks is a set of hidden embedding vectors that capture the latent semantics of each objective. They are then fed into a mixture attention network to calibrate the outputs of HyperNetworks and jointly predict the objective values $\{\tilde{y}_1, \tilde{y}_2 \dots, \tilde{y}_n\}$ (see Figure 4). Specifically, we utilize the attention mechanism (Vaswani et al. 2017) and assigns different attention values to different objectives to model the heterogeneous relationships between them.

Specifically, the architecture of the Mixture of HyperNetwork module (Module 1 in Figure

4) is presented in Figure 5 and works as follows. It takes the inputs of product embeddings and consumer state representations shown at the bottom of Figure 5, which we denote as s_u and s_i , and generates predictions of multiple objectives $\tilde{y} = \{\tilde{y}_1, \tilde{y}_2, \dots, \tilde{y}_n\}$ for consumer u as:

$$\tilde{y} = \sum_{k=1}^n g(f_k([s_u; s_i])) \quad (1)$$

where $f_k(\cdot)$ represents the k -th hypernetwork for the k -th objective, $[s_u; s_i]$ represents the concatenation of latent embeddings for consumer u and product i that we obtained from the embedding layer in Figure 4, and $g(\cdot)$ is the mixture attention network that calibrates the outputs of hypernetworks for predicting objective values. Within the network $g(\cdot)$, the attention values e_{kl} for the k -th objectives with respect to the l -th hypernetwork is computed following the self-attention mechanism (Shaw et al. 2018) as follows:

$$e_{kl} = \frac{\exp(d(W_k, W_l))}{\sum_{j=1}^n \exp(d(W_k, W_j))}$$

where W_l is the output of the l -th hypernetwork and $d(\cdot, \cdot)$ is the Euclidean distance metric. The entire module is optimized by minimizing the difference between the predicted values \tilde{y}_k and the ground truth y_k :

$$L(\text{prediction}) = \sum_{k=1}^n |\tilde{y}_k - y_k| \quad (2)$$

Specific configurations of the module, such as the size and the structure of each neural network, will be discussed in Section 5. Note that the novelty of the proposed architecture presented in Figure 5 lies in taking the existing HyperNetwork technique (Ha et al. 2016) for modeling individual objectives and combining them into a multi-objective predicting network by

using the mixture-attention mechanism described in this section. Next, we will present another module in our framework for combining these predicted objective values into a utility function used for providing multi-objective recommendations.

4.3 Deep Contextual Reinforcement Learning

As motivated in the last section, to determine the optimal balance between different objectives that work best for each consumer and each product under each specific circumstance, it is crucial to take into account personalized and contextualized consumer preference in multi-objective recommendations. In this section, we present a *Deep Contextual Reinforcement Learning* method (see Module 2 in Figure 4) to determine the weights of multiple objectives. Our method is motivated by Reinforcement Learning (RL), which can effectively model personalized preferences in recommender systems (Afsar et al. 2022), as discussed in Section 3.4. However, our method also incorporates contextualized information into RL to address contextual fluctuations of consumer preference towards different objectives.

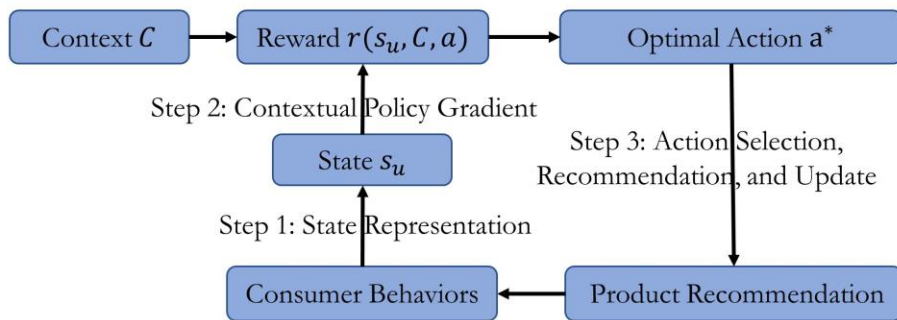

Figure 6: Overview of the Deep Contextual Reinforcement Learning Module

Specifically, our module consists of a three-stage learning process, as shown in Figure 6, and works as follows. In Step 1 (*State Representation*), we construct the representation of

consumer state s_u as a latent embedding for effectively modeling personalized preference. While there are many DL-based models in the literature to achieve this task, such as RNN, LSTM or Transformer (Sun et al. 2019), we present a *Self-Attentive Time-LSTM* method in this paper that provides the following modeling advantages: it (1) effectively models the temporal dynamics of consumer behaviors through the sequential learning technique (Wang et al. 2019); (2) captures duration information between consumers’ consecutive transactions to better understand the sequential consumer decision-making process (Mei & Eisner 2017; Zhu et al. 2017); and (3) utilizes the Self-Attention mechanism (Shaw et al. 2018) to assigns different weights to transactional records to account for different levels of their impact on consumer decisions. As a result, it models consumer state and captures the essence of personalized information more effectively than other alternatives, including RNN, LSTM and the standard transformer model, which we will demonstrate in Section 5.5.

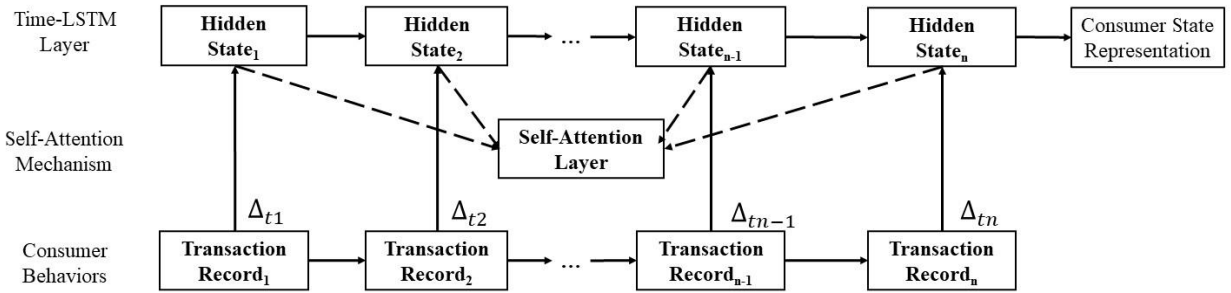

Figure 7: Illustration of the Self-Attentive Time-LSTM Model for Consumer State Representation

Our Self-Attention Time-LSTM model is illustrated in Figure 7 and works as follows. We denote the set of consumers as $U = \{u_1, u_2 \dots, u_n\}$ and the set of products as $I = \{i_1, i_2 \dots, i_n\}$. The transaction record is denoted as $H = \{(TR_1, \Delta_{t1}), (TR_2, \Delta_{t2}) \dots, (TR_n, \Delta_{tn})\}$ for each consumer, where TR_k represents the k -th product in the transaction records, and Δ_{tk} stands for

the time interval before the purchase of the k -th product. The LSTM network structure consists of three components that control the information flow during the sequential learning process, namely the input gate, forget gate, and output gate, which we denote in our model as i_k , f_k and o_k respectively. $x_k = (TR_k, \Delta_{tk}, C_k)$, where C_k is the contextual information vector, and h_k represent the input transaction record vector and the output hidden vector, and c_k is the cell activation vector. We denote the activation function for each gate and each vector as σ_i , σ_f , σ_o , σ_c , σ_h , the weight parameters as W_{xi} , W_{xf} , W_{xo} , W_{hi} , W_{hf} , W_{ho} , and the bias terms as b_i , b_f , b_o respectively. To incorporate the time interval information during the training process, we add a time gate T_k to the LSTM. Then we update each gate, activation cell, and hidden vector as:

$$\begin{aligned}
i_k &= \sigma_i(\widetilde{x}_k W_{xi} + h_{k-1} W_{hi} + b_i) \\
f_k &= \sigma_f(\widetilde{x}_k W_{xf} + h_{k-1} W_{hf} + b_f) \\
o_k &= \sigma_o(\widetilde{x}_k W_{xo} + h_{k-1} W_{ho} + b_o) \\
T_k &= \sigma_t(\widetilde{x}_k W_{xt} + \sigma_\Delta(\Delta_k W_{ht}) + b_t) \\
c_k &= f_k \otimes c_{k-1} + i_k \otimes T_k \otimes \sigma_c(\widetilde{x}_k W_{xc} + h_{k-1} W_{hc} + b_c) \\
h_k &= o_k \otimes \sigma_h(c_k)
\end{aligned}$$

Note that the network inputs \widetilde{x}_k are calibrated through the self-attention mechanism as the weighted sum of the linearly transformed inputs x_k , before being fed into the Time-LSTM:

$$\begin{aligned}
\widetilde{x}_k &= \sum_{i=1}^k e_{ki} \times W_{attention} x_i \\
e_{ki} &= \frac{\exp(d(x_k, x_i))}{\sum_{j=1}^n \exp(d(x_k, x_j))}
\end{aligned}$$

where $W_{attention}$ stands for parameters of the self-attention layer, e_{ki} represents the weight coefficients, and $d(x_k, x_i)$ is the similarity between inputs x_t and x_i . By iteratively computing

hidden states h_k of Self-Attentive Time-LSTM, we obtain the hidden state h_n at the end of the transaction records based on the aforementioned equations, which constitutes the consumer state $s_u = h_n$, as shown in Figures 6 and 7.

The novelty of the Self-Attentive Time-LSTM lies in that it considers both the time information and the sequential behaviors to model the consumer state representation. It also considers the heterogeneous impact of past transactions towards current consumer decision-making process, making it significantly different from alternative methods in the literature, including LSTM, RNN, GRU, and Transformer. We will also demonstrate the performance advantages of our method in Section 5.5.

Based on the consumer state described in Step 1, we next present our proposed *Contextual Policy Gradient* method in Step 2 of the module presented in Figure 6 to quantify the value or benefit of taking a specific action a in a given state s_u . In the reinforcement learning literature, such benefits are usually determined by Q-value $Q(s_u, a)$ following the Q-learning approach (Watkins & Dayan 1992; Mnih et al. 2015), so that we can select the optimal action that optimizes the Q-value. However, this method only works well for discrete actions within a bounded action space, while in our setting, each action is a set of objective weights that can take arbitrary values, resulting in a large continuous action space. In addition, existing methods do not incorporate the contextual information into the reinforcement learning process. To this end, our Contextual Policy Gradient method works by developing two sets of neural networks: the actor network $\mu(s_u, C|\theta^\mu)$ that selects a certain action a based on state s_u and context C ; and the critic

network $Q(s_u, a, C|\theta^Q)$ that generates the Q-value of the selected action a based on state s_u and context C . θ^μ and θ^Q represents the parameters for the actor and critic networks respectively, which are optimized following the policy gradient technique (Lillicrap et al. 2016) that works as follows. A policy π in reinforcement learning is defined as the probability distribution of actions given a state, i.e., $\pi_\theta(a|s_u)$. Since we cannot optimize the action a directly in this case, we will optimize its parameterized distribution instead to maximize the expected return

$E[Q(s_u, C, \mu(s_u, C|\theta^\mu))]$ of each action. According to (Sutton & Barto 2018), the derivative of the expected return can be calculated by applying the chain rule to the objective function:

$$\nabla_{\theta^\mu} J(\theta^\mu) \approx \frac{1}{N} \sum_t \nabla_a Q(s_u, a = \mu(s_u|\theta^\mu)) \times \nabla_{\theta^\mu} Q(s_u, \mu(s_u|\theta^\mu)) \quad (4)$$

The critic network is optimized by minimizing the prediction error of the expected return, i.e.,

$$L(\theta^Q) = \frac{1}{N} \sum_t |Q(s_u, C, a|\theta^Q, t) - Q(s_u, C, a)|^2 \quad (5)$$

In addition, we update the parameters θ^μ and θ^Q based on equations (4) and (5) following a soft updating mechanism (Van et al. 2016) to improve the learning stability:

$$\theta^\mu = \tau\theta^\mu + (1 - \tau)\theta^{\mu'}, \quad \theta^Q = \tau\theta^Q + (1 - \tau)\theta^{Q'} \quad (6)$$

where θ^μ and θ^Q are primary parameters for both networks that will be updated every learning iteration; $\theta^{\mu'}$ and $\theta^{Q'}$ are target parameters that will be fixed for some iterations and synchronized with θ^μ and θ^Q periodically; and τ is the temperature parameter that controls for the update rate ($\tau \ll 1$). Eventually, we use the primary networks to select the action and employ the target networks to estimate the Q-values.

The novelty of our Contextual Gradient Method lies in that we incorporate the contextual information when determining the most suitable action based on the consumer state, and conduct the reinforcement learning through the policy gradient technique to tackle the problem of large action space, enabling us to produce recommendation in an effective and efficient manner.

Finally, in Step 3 (*Recommendation and Update*) presented in Figure 6 (and shown in Figure 4), we produce recommendations by selecting those products with the highest utility values $\sum_k \alpha_k \widetilde{y}_k$, where $\{\widetilde{y}_1, \widetilde{y}_2, \dots, \widetilde{y}_n\}$ are predicted by the ‘‘Mixture of HyperNetwork’’ module, and $\{\alpha_1, \alpha_2, \dots, \alpha_n\}$ are estimated by the ‘‘Deep Contextual Reinforcement Learning’’ module, as shown in Figure 4. Based on the consumer feedback, we update the state representation s_u , and context C to produce subsequent recommendations.

4.4 Theoretical Properties of Our DeepPRL Model

In this section, we will present the theoretical properties of our method, which are related to the existence of pareto optimality in our problem and the performance level of our model.

Proposition 1 (Existence of Pareto Optimality) For any multi-objective recommendation task formulated in Section 3.1, where the utility value $\sum_k \alpha_{u,i,k} y_{u,i,k}$ involves n objectives

$\{y_{u,i,1}, y_{u,i,2}, \dots, y_{u,i,n}\}$ associated with product i and consumer u , there exists a pareto optimal solution $\widetilde{\alpha} = \{\widetilde{\alpha}_{u,i,1}, \widetilde{\alpha}_{u,i,2}, \dots, \widetilde{\alpha}_{u,i,n}\}$ such that the aggregated utility across all consumers and all products $\sum_u \sum_i \sum_k \widetilde{\alpha}_{u,i,k} y_{u,i,k}$ is maximized.

Proof. According to the definition of pareto optimality in multi-objective optimization (Navon et al. 2021), it is equivalent to show that there exists $\widetilde{\alpha}$ such that $\sum_u \sum_i \sum_k \widetilde{\alpha}_{u,i,k} \nabla L_k(u, i, y_{i,k}) = 0$,

where $L_k(u, i, y_{i,k})$ is the loss function for optimizing the k -objective when recommending product i to consumer u . Since the utility is modeled as a linear function, the loss function (Equation (2) in Section 4.2) becomes continuously differentiable and its Jacobian becomes invertible. Then based on the implicit function theorem (Krantz & Parks 2002), there exists a neighborhood U such that for any $\alpha \in U$, $\sum_u \sum_i \sum_k \alpha \nabla L_k(u, i, y_{i,k}) = 0$, Q.E.D.

Proposition 2 (Performance Bound) For any multi-objective recommendation task formulated in Section 3.1, the difference between the loss (empirical risk) ε achieved by our DeepPRL model in Section 4, and the minimum loss ε^* achieved by the pareto optimal is bounded.

Proof. The main idea is to decompose the differences between the empirical risks $|\varepsilon - \varepsilon^*|$ into multiple disjoint components, and obtain the upper bound for each one respectively. Specifically, for n different objectives, we denote the predictive function for each objective as f_1, f_2, \dots, f_n , which are all associated with our DeepPRL model. We also denote the loss function as $l(\cdot)$, and the consumer state representation as h . Then for input X and output Y , we can express the two empirical risk terms as follows:

$$\varepsilon(h, f_1, f_2, \dots, f_n) = \frac{1}{n} \sum_{i=1}^n E_{(X,Y) \sim \mu_i} l(f_i(h(X)), Y)$$

$$\varepsilon^*(h, f_1, f_2, \dots, f_n) = \min_{h \in H, (f_1, f_2, \dots, f_n) \in F} \varepsilon(h, f_1, f_2, \dots, f_n)$$

where μ_i is the measure for the i -th objective, H and F are the functional spaces for h and f_i . For the case of pareto optimality, we denote the optimal predictive function as $f_1^*, f_2^*, \dots, f_n^*$, and:

$$\varepsilon - \varepsilon^* = \left(\varepsilon(h, f_1, f_2, \dots, f_n) - \frac{1}{nT} \sum_{it} l(f_i(h(X_{it})), Y_{it}) \right) +$$

$$\left(\frac{1}{nT} \sum_{it} l(f_i(h(X_{it})), Y_{it}) - \frac{1}{nT} \sum_{it} l(f_i^*(h(X_{it})), Y_{it}) \right) +$$

$$\left(\frac{1}{nT} \sum_{it} l(f_i^*(h(X_{it})), Y_{it}) - \frac{1}{n} \sum_{i=1}^n E_{(X,Y) \sim \mu_i} l(f_i^*(h(X)), Y) \right)$$

The first term is bounded by $\sup_{h \in H, (f_1, f_2, \dots, f_n) \in F} \varepsilon(h, f_1, f_2, \dots, f_n) - \frac{1}{nT} \sum_{it} l(f_i(h(X_{it})), Y_{it})$, which,

according to the Benefits of Multi-Task Representation Learning (Theorem 13 in (Maurer et al. 2016)), will be further bounded by a constant that only involves $|\sup_{h \in H} h(X)|$. The second term is

bounded, since the predictive function f_i in our model are learned using the Stochastic Gradient Descent method to approximate the optimal function f_i^* , and the Convergence Theorem (Bottou 1998) states that the difference between them will be bounded by a constant that only involves the input X and the learning rate. Finally, the third term only involves nT random variables

$l(f_i^*(h(X_{it})), Y_{it})$ sampled from a uniform distribution; accordingly to the Hoeffding's

Inequality (Hoeffding 1994), the difference will be bounded with probability $1 - \frac{\delta}{2}$ by

$\sqrt{\ln\left(\frac{2}{\delta}\right) / (2Tn)}$. A union bound of these three components will then complete the proof. Q.E.D.

In conclusion, the two propositions presented in this section demonstrate that the pareto optimality exists, and that our DeepPRL model is capable of achieving a performance level where its difference from the pareto optimality is bounded. Besides theoretical properties, we will also provide empirical evidence to demonstrate the benefits of DeepPRL in the next section.

4.5 Summary of Our Proposed DeepPRL Model

In Sections 4.2 and 4.3, we presented the Mixture of HyperNetwork and the Deep Contextual Reinforcement Learning modules of our proposed method, which provides a

systematic mechanism of estimating multiple objective values and balancing between these objectives. In contrast to the existing methods, our method explicitly captures the dynamic relationships between multiple objectives through hypernetworks, and determines the balance between them in a personalized and contextualized manner, thus providing the following benefits. First, it enables us to reach the level of performance that significantly outperforms existing state-of-the-art solutions, which we will demonstrate in Sections 5 and 6. Second, it enhances the level of personalization and contextualization in multi-objective recommendations by selecting the appropriate set of objective weights for *each* consumer under *each* contextual scenario, resulting in significant performance improvements, as demonstrated in Section 6. Third, it automatically and effectively identifies consumer preference towards different objectives from archival records, without requiring any explicit consumer feedback through surveys, as was done in the literature (Swait et al. 2018). Fourth, by utilizing the Contextual Policy Gradient method to also incorporate future rewards when selecting the optimal actions (rather than only immediate rewards), our proposed model also optimizes the long-term (versus only the short-term) performance of multiple objective recommendations, which is particularly useful for many platforms relying on the business performance over the long run (Zou et al. 2019). Finally, we mitigate the data sparsity and scalability problems by updating the weights in real-time through deep learning techniques, making our method even more suitable for large-scale industrial platforms, which we illustrate through the online experiments in Section 6. Our model is also general in the sense that it works for any number of objectives since action a can

represent an arbitrary number of weights, making it particularly useful in real world applications with more than two objectives (Zheng & Wang 2022). In fact, we conduct our online experiment to optimize three conflicting objectives for the platform, and manage to achieve significantly better recommendation performance.

Table 1: Comparisons with Selected State-of-the-Art Methods in the Literature

To further illustrate the novelty of our proposed model, we compare it with some previously proposed methods across the following five dimensions (columns) in Table 1: (1) **Relationships between Objectives**, whether the focal model explicitly models the relationships between different objectives during the recommendation process; (2) **Dynamic Weighting**, whether the focal model uses a fixed vs. a dynamic set of objective weights for producing recommendations; (3) **Contextual Information**, whether the focal model incorporates the contextual information

during the recommendation process; (4) **Pareto Frontier Learning**, whether the focal model optimizes one single objective, or optimizes the pareto frontier of multiple objectives; (5) **Long Term Performance Optimization**, whether the focal model optimizes only the short-term performance, or it also optimizes the performance in the long run. We can observe from Table 1 that our model incorporates all the five important aspects of the multi-objective recommendation task. As a result, it leads to significant performance improvements over other alternatives, which we will demonstrate through offline and online experiments in Sections 5 and 6.

5 Offline Experiment

5.1 Multi-objective Recommendation Tasks

To evaluate the recommendation performance, we apply our proposed method to the following three multi-objective recommendation tasks in real-world applications, each with two targeted objectives, in our offline experiments. We will also study a recommendation task with three targeted objectives in our online experiment, which we will describe in detail in the next section.

(1) **Short Video Recommendations at Alibaba-Youku.** As a major video streaming platforms in China (Li et al. 2020), Alibaba-Youku provides multi-objective short video recommendations by optimizing the Video View (VV, number of videos viewed per session) and the Dwell Time (DT, watching time spent per session) objectives, which are the most relevant for generating revenues by the platform. As explained in Section 1, these two objectives conflict with each other, as focusing on VV leads the system to recommend shorter videos to encourage finishing watching each video quickly, which is sub-optimal for DT.

(2) **Restaurant Recommendations at Yelp.** Yelp is a popular local business review site

(Luca 2016). We focus on its multi-objective restaurant recommendation service by examining the relevance vs. novelty objectives in this study. On one hand, the most relevant restaurants usually fit well with consumers' tastes; on the other hand, it is also beneficial to provide consumers with diversified experiences of other types of restaurants that they haven't explored yet, which might fit their culinary preferences even better.

(3) Music Recommendations at Spotify. Spotify is a music streaming service that produces music recommendations based on the following two objectives: "listening percentage" (the percentage of a piece of music the consumer listened to) and "saved" (whether the consumer saved a piece of music or not) (Mehrotra et al. 2019). While these two metrics are positively correlated, they might still part ways, as a newly released piece of music generally has a higher listening percentage due to the novelty factor, but the saved metric might not necessarily be high.

For all these three datasets, we normalize the values of each recommendation objective to a scale of 0 and 1. We use the demographics and other characteristics of consumers as the personalized information in our model. In addition, we utilize the last 10 purchased products, as well as the purchasing date & time as the contextual information, following the standard industrial practice (Gomez-Uribe & Hunt 2015). The descriptive statistics of these datasets are listed in Table 2. As they represent three very different recommendation applications, and the three pairs of objectives in these applications constitute very heterogeneous relationships (Pearson Coefficients -0.238, -0.596, and 0.369 between the objective pairs respectively), the

offline results would be able to demonstrate robustness and generalizability of our model¹.

Dataset	Alibaba-Youku	Yelp	Spotify
# Of Transaction Records	1,806,157	2,254,589	970,013
# Of Consumers	46,143	76,564	294,469
# Of Products	53,657	75,231	81,948

Table 2: Descriptive Statistics of Three Datasets for Offline Experiments

5.2 Baseline Models

In our experiments, we compare our proposed method with the following three groups of eight state-of-the-art baseline recommendation models, where the objective weights are all determined in a *static* manner through Bayesian Hyperparameter Optimization (Snoek et al. 2012):

(1) **Multi-Objective Recommendation Baselines**, which include Multi-Objective Linear Upper Confidence Bound (MO-LinCB) (Mehrotra et al. 2020), Multi-Objective Reinforcement Learning (MORL) (Abels et al. 2019), and Progressive Layered Extraction (PLE) (Tang et al. 2020). These multi-objective recommendation models are commonly adopted in two-sided marketplaces (Mehrotra et al. 2019) and work by balancing between different objectives using fixed weights or a set of fixed rules.

(2) **Multi-Task Recommendation Baselines**, which include Multi-gate Mixture-of-Experts (MMOE) (Ma et al. 2018), Mixture of Sequential Experts (MoSE) (Qin et al. 2020), and Shared-Bottom (Ruder 2017) models. These models primarily focus on simultaneously optimizing multiple machine learning tasks (not limited to recommendations), and we apply them to the multi-objective recommendation application by jointly predicting and aggregating multiple

¹We have shared the codes of our model at https://anonymous.4open.science/r/Multi_Objective-CF5F

objectives through a linear utility function with fixed weights.

(3) **Deep Reinforcement Learning Baselines**, which include REINFORCE (Chen et al. 2019) and DRN (Zheng et al. 2018) models. They utilize Deep Q-Learning or Top-K Correction techniques to provide recommendations that maximize the total reward of a given policy. Although these two methods are single-objective, nevertheless we have chosen them as baselines to demonstrate that the advantages of our model do not come from the use of deep reinforcement learning technique alone; instead, it requires a careful combination of “mixture of hypernetworks” and “deep contextual reinforcement learning” methods that we propose in the paper to produce satisfying multi-objective recommendations.

We determine the optimal hyperparameter values and configurations for our model through Bayesian Hyperparameter Optimization (Snoek et al. 2012) and the hyperparameter sensitivity analysis presented in Section 5.6. As a result, Self-Attentive Time-LSTM includes two fully-connected layers with a batch size of 32. The HyperNetwork model is formulated as 3 fully-connected layers with the Sigmoid activation function. The Contextual Policy Gradient model is constructed as 3 fully-connected hidden layers with the Sigmoid activation function. Both the actor and critic networks are formulated as fully-connected networks. These models are optimized using the Stochastic Gradient Descent with a learning rate of 0.01. Finally, we select the discount rate γ as 0.99, the temperature τ as 0.05, and the number of hidden units as 64. Recommendations are evaluated by time-stratified 5-fold cross-validation with multiple runs.

Table 3: Offline Experiments on Three Multi-Objective Recommendation Tasks. Improvements are shown over the second-baseline models (underlined). *** $p < 0.01$.

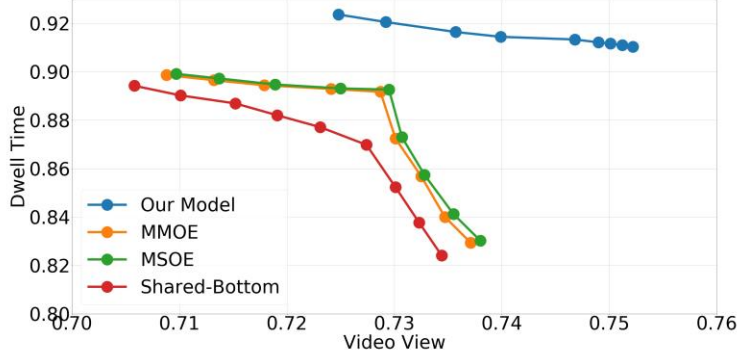

5.3 Experimental Results

The offline experimental results are shown in Table 3, where we can observe that our DeepPRL model significantly outperforms all three groups of eight baseline models across all recommendation tasks. In particular, when comparing with the second-best baselines, our model achieves significant improvements in *both* objectives *simultaneously* (e.g., 2.55% in the VV metric and 2.27% in the DT metric for the Alibaba-Youku dataset) across *all the three* applications, as we *dynamically* select the most appropriate objective weights for *each* consumer. It also demonstrates the power of modeling multiple objectives simultaneously rather than focusing only on one objective. As these improvements are significant across all three tasks and six different objectives, regardless of their relationships with each other (as evidenced by different Pearson Coefficient values), we demonstrate the generalizability and flexibility of our model to *dynamically determine evolving balances between the objectives*, thus *significantly outperforming state-of-the-art baselines for all objectives in multi-objective recommendations*. We would also like to point out that the improvements that we achieved in the range of 1% - 23% (see Table 3) are considered to be very significant in the industry (Gomez-Uribe & Hunt 2015).

To further demonstrate the robustness of our method under different experimental settings, we have also conducted sparsity, sensitivity, and scalability analyses reported in Section 5.6.

5.4 Pareto Frontier Analysis

In this section, we provide empirical evidence that our model dominates the pareto frontiers of existing multi-task learning methods, such as MMOE, MSOE, and Shared-Bottom. To obtain their pareto frontiers in our experiments, we follow the established protocols in the literature (Ribeiro et al. 2014 ;Zheng & Wang 2022), and run those baseline models multiple times - each time, we set different values for objective weights by changing the them gradually from 0 to 1, and record their performance accordingly, as we show in Figure 7(a-c). When we set the weight for one objective as 1 and all others as 0, we will achieve the best performance for that objective but potentially the worst for all others. When we gradually decrease the weight for that objective and increase the weights for others, we will observe the performance degradation on that objective as well as the performance improvements on all other objectives. For our proposed DeepPRL model, however, the objective weights are dynamically determined by the deep learning model; therefore, we obtain its pareto frontier by running the neural network multiple times with different network initializations, and record the model performance respectively, following the practice in (Abels et al. 2019).

(a) Pareto Frontier Plot for the Alibaba-Youku dataset

(b) Pareto Frontier Plot for the Yelp dataset

(c) Pareto Frontier Plot for the Spotify dataset

Figure 7: Pareto Optimality Analysis with Different Sets of Importance Weights

We observe from Figure 7 that our model performs significantly better than all baseline methods in terms of *both* objectives across all the three datasets and dominates their pareto

frontiers. In this respect, our model manages to improve the recommendation across multiple objectives *simultaneously* over the baseline models, even for those conflicting ones such as VV and DT in the Alibaba-Youku dataset. Therefore, we empirically demonstrate the advantages of our proposed model in various recommendation settings.

5.5 Ablation Study of Our Proposed Model

Since our model consists of two modules: the “Mixture of HyperNetwork” module for predicting the objective values, and the “Deep Contextual Reinforcement Learning” module for determining the objective weights, we will conduct a series of ablation studies in this section to demonstrate the effectiveness of these modules and justify our design choices. Specifically, we compare the performance of our model with the following variants (where we replace each component with an alternative design and keep the other intact):

Model Variants	Descriptions
Variant 1 (Time-LSTM)	We replace the Self-Attentive Time-LSTM component with the Time-LSTM model for state representations, which does not utility the self-attention mechanism.
Variant 2 (Self-Attention LSTM)	We replace the Self-Attentive Time-LSTM component with the Self-Attention LSTM model for state representations, which does not model the dwell time.
Variant 3 (Transformer)	We replace the Self-Attentive Time-LSTM component with the Transformer model for state representations.
Variant 4 (Shared-Bottom)	We replace the Mixture-of-HyperNetwork component with the Shared-Bottom model (Ruder 2017) to predict objective values.
Variant 5 (Cross Stitch)	We replace the Mixture-of-HyperNetwork component with the Cross Stitch model (Misra et al. 2016) to predict objective values.
Variant 6 (DQN)	We replace the Contextual Policy Gradient component with the DQN model (Mnih et al. 2015) to produce objective weights.
Variant 7 (REINFORCE)	We replace the Contextual Policy Gradient component with REINFORCE (Chen et al. 2019) to produce objective weights.

Table 4: Summary of Model Variants in the Ablation Study

We report the results in Table 5, where we observe that our model significantly outperforms

all seven variants. Specifically, improvements over Variant 1, 2, and 3 are well over 2%, indicating the importance and effectiveness of Self-Attention Time-LSTM for modeling consumer state representations. In addition, improvements over Variant 4 and 5 are around 1%, demonstrating the superiority of the Mixture-of-HyperNetwork module for predicting the values of multiple objectives. Finally, we observe over 2% improvements over Variant 6 and 7, as the Contextual Policy Gradient module dynamically updates the recommendation policy through the policy gradient to maximize the agent return. To sum up, these ablation studies demonstrate that we need all the novel components described in this paper and their proper integration into a coherent model to produce superior recommendation performance.

5.6 Sparsity, Sensitivity, and Scalability Analysis

To further demonstrate the robustness of our framework under different experimental settings, we conduct additional sparsity, sensitivity, and scalability analysis in this section. To start with, we randomly sample three subsets from the Spotify dataset with different sparsity levels ($Sparsity = (\# \text{ of Transaction Records}) / (\# \text{ of Consumers} \times \# \text{ of Products})$), as shown in Table 6, and we implement those models in our framework as well as baseline models on them.

Dataset	Spotify-1	Spotify-2	Spotify-3
# Of Transaction Records	970,013	91,523	11,921
# Of Consumers	294,469	12,373	865
# Of Products	81,948	55,903	9,588
Sparsity	0.004%	0.0132%	0.1437%

Table 6: Descriptive Statistics of Different Versions of the Spotify Dataset for Sparsity Analysis

The results in Table 7 confirm that our model significantly outperforms baselines under all three datasets with different sparsity levels and different data sizes. We also observe that our model achieves the most improvements on the subset (Spotify-3) with the highest sparsity level and the lowest data size, demonstrating its effectiveness in handling the data-sparsity problem.

Table 7: Sparsity Analysis on Three Multi-Objective Recommendation Tasks. Improvements are shown over the second-baseline models (underlined). *** $p < 0.01$.

We further conduct the sensitivity analysis to study how different values of the discount rate γ (in Equation 3), the temperature parameter τ (in Equation 6), and the number of hidden units affect the performance of our model. As shown in Figure 8(a-c), the performance remains relatively steady across different hyperparameter settings, as the fluctuations are only under 0.3% and small in their absolute values. Our model is also largely insensitive to the hyperparameter values (except for the extreme case when the number of hidden units is less than 32), and the

performance can be further improved when choosing the optimal values ($\gamma = 0.99, \tau=0.95$, Number of Hidden Units=64), as we did in Section 5.2.

(c) Sensitivity Study on the Temperature Parameter τ . Y-axis Shows the Average Value of the Objective.

Figure 8: Sensitivity Study on Alibaba-Youku dataset with Different Hyperparameter Selection

Finally, to further demonstrate practicality of our model, we conduct the scalability analysis where we train our model using a personal laptop on multiple randomly selected subsets of three offline datasets with different data sizes ranging from 100 to 1,000,000 records. We then record

the training time for 100 epochs on each subset and plot it in Figure 9, where we observe that our model scales linearly in the number of data records, and this linear scalability comes from our use of deep learning techniques, which are scalable and flexible in practice. In fact, according to (Yang & Amari 1998), the time complexity for training our model using natural gradient descent is only $O(N)$, where N is data size.

To summarize, our proposed model provides scalable and effective recommendations and successfully deals with the data-sparsity problem, making it particularly useful in industrial settings, as we also demonstrate through the online controlled experiments in the next section.

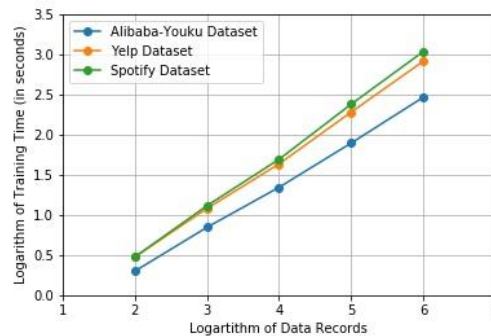

Figure 9: Scalability Performance Analysis on Three Offline Dataset.

6 Online Experiment

6.1 Empirical Context and Identification

To demonstrate the business impact of our proposed model, we conduct a large-scale online controlled experiment on live customers at Alibaba-Youku. Based on the company guidelines, we study the multi-objective recommendation task based on three objectives of Click-Through Rate (CTR), Video View (VV), and Dwell Time (DT). The relationships between them are complex and heterogeneous, as discussed in Section 1: the objectives of VV and DT are usually

conflicting with each other, while literature has identified positive correlation between the objectives of CTR and VV (Li et al. 2020).

We randomly split consumers into the control group and the treatment group, where they receive video recommendations served by our DeepPRL model and the latest production system (a modified version of MMOE (Ma et al. 2018) with static objective weights) respectively. The randomized splitting is achieved through binary hashing on User IDs, which ensures that the balance of demographics and characteristics of consumers in both groups. This has been verified by the engineering team of Alibaba and our Wilcoxon rank-sum test in Table 8 below, where we compare the consumer feature distribution between the two groups. We can observe from the table that the differences for each consume feature are all statistically insignificant (having p-value greater than 0.05 for all cases). Therefore, we further validate the randomized setting in our online experiment, which enables us to estimate the treatment effect directly. In addition, consumers are unaware of their treatment assignment during the experiment, as the GUI remains the same for both groups, therefore eliminating the novelty effect.

Consumer Features		Mean	25th percentile	Median	75th percentile	Variance	p-value
Gender	Treatment	0.002	-1.000	1.000	1.000	0.990	>0.05

	Control	20.565	8.000	19.000	27.000	8.490	

Table 8: Consumer feature-level summary statistics for the control and treatment groups.

Our experiment was conducted during the entire month of January 2021, involving 63,361 consumers and their 30,714,995 watching records. The consumer pool and experiment duration are determined following the standard protocols at Alibaba and deemed to be sufficient to demonstrate the potential effects of our model, according to the director of the experiment team at Alibaba. In our analysis, we use the OLS technique to specify the three business objectives of VV_{ijt} , DT_{ijt} , and CTR_{ijt} for consumer i and video j at time t :

$$Objective_{ijt} = \alpha_0 + \alpha_1 Treatment_i + \vec{\alpha}_2 \vec{X}_j + \vec{\alpha}_3 \vec{Y}_i + D_t + \varepsilon_{ijt} \quad (8)$$

where $Treatment_i$ is the dummy variable indicating the consumer group assignment, \vec{X}_j represents consumer features, \vec{Y}_i represents video features, and D_t represents the time-fixed effects. We list the detailed consumer and video features used in our analysis in Table 9 below.

Category	Variable	Description	Format
Consumer Features	Gender	Gender of the consumer	Categorical
	Age	Age of the consumer	Numerical
	Province	The province where the consumer lives in	Categorical
	City	The city where the consumer lives in	Categorical
	Operating System	The operation system on the consumer's device when logging into the platform	Categorical
	VIP Status	Whether the consumer subscribed to the premium service of the platform	Categorical
	Active Days	The number of days that the consumer has logged into the platform over the past month	Numerical
Video Features	Genre	Genre of the video	Categorical
	View Count	The total number that the video has been viewed over the past month	Numerical
	Comment Count	The total number that the video has been viewed over the past month	Numerical
	Release Days	The number of days that the video has been released on the platform	Numerical
	Video Length	The duration of the video	Numerical

Table 9: Summary of Consumer and Video Features Recorded in the Online Experiment.

6.2 Main Results

We present the regression analysis in this section that directly compares consumers' video-watching behaviors between the treatment and control groups. As Table 10 demonstrates, our model significantly increases video consumption compared with the latest production model, as we observe significantly positive treatment coefficients all three objectives. In particular, in each session, consumers in the treatment group increased the amounts of viewed videos (VV) by 0.474 (or 5.09%, since the average VV value is 9.32), the average watching time (DT) by 45.836 seconds (or 7.11%, since the average DT value is 644.67), and the average click-through rates (CTR) by 2.36% (having $p < 0.01$ in all cases). This significant improvement is due to our model's capability of balancing these three conflicting objectives in a personalized and contextualized manner. In addition, we have confirmed with the company that there are no significant differences between the churn rates of both consumer groups throughout the experiment, demonstrating that performance improvements indeed come from the benefits of our model, rather than the abandonment effect. It also does not incur additional computational costs for the company. Furthermore, our model has demonstrated a very substantial economic impact, leading the management of the company to consider moving our model into production.

6.3 Long-Term Analysis

As discussed in Section 4.3, an important advantage of the “Deep Contextual Reinforcement Learning” module in our model lies in its ability to optimize long-term performance. To validate this point, we conduct the long-term analysis in this section by estimating the treatment effect on a daily basis following the same identification model in equation (8). We have confirmed that there is no significant difference between consumer groups at any time in our experiment. Note that our one-month online experiment is sufficient to demonstrate the long-term impact on the platform (in comparison, most A/B tests are conducted over one week at Alibaba, thus making our experiment relatively long-term for the company).

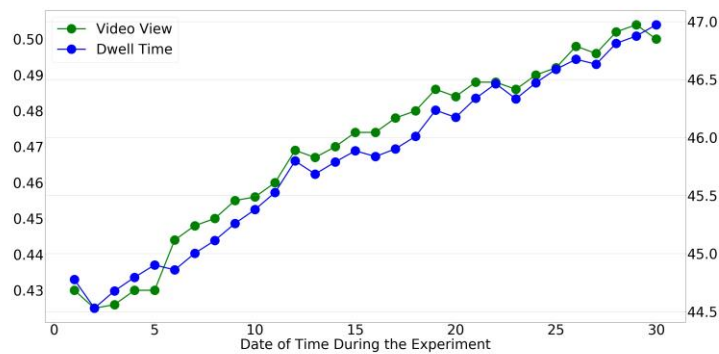

Figure 10: Long-Term Analysis of Our Model in the Online Experiment. The Y-axis Shows the Average Treatment Effect on the Objective.

The results are presented in Figure 10, where the x-axis represents the date in our experiment, and the y-axis denotes the treatment effect on the VV and DT metrics (we have similar observations for the CTR metric as well). We observe from Figure 10 that our model significantly outperforms the production system throughout the entire experiment without any performance degradation. Furthermore, the improvements gradually increase since day 5 of our

experiment, and it eventually reaches the level of 0.5 (or 6%) improvement in the VV metric and 47 seconds (or 8%) improvement in the DT metric by the end of our experiment. As these improvements consistently remain significant, we demonstrate the superiority of our model and its novel module for improving long-term multi-objective recommendation performance.

6.4 Robustness Check

To further validate our findings, we also conduct an extensive set of robustness checks of our performance, where we replicate our previous analysis under the following alternative settings:

(a) We include different combinations of consumer features, video features, and time-fixed effects in the regression models to evaluate the treatment effects.

(b) We exclude those records of the premium video content in our analysis that are only available to VIP consumers, who might be more willing to watch those videos due to their loyalty to the platform and the exclusivity of the content.

(c) We exclude those records from new consumers who just registered to the platform less than a week before our experiment started, as they might be more willing to watch recommended videos due to the novelty effect. We also drop those records from the newly released videos, which might be appealing to the consumers due to the recency effect.

Consumers	63,361	63,361	63,361	63,361	63,361	63,361
Observations	30,714,995	30,714,995	30,714,995	30,714,995	30,714,995	30,714,995

Table 14: Average Treatment Effect when Excluding Premium Video Content, New Consumers and Newly Released Videos. Robust standard errors in parentheses. * $p < 0.1$; ** $p < 0.05$; *** $p < 0.01$

As shown in Tables 11, 12, 13, and 14, our results are not affected by the exclusion of feature information or fixed effects in the estimation process, and our results also remain robust when

we exclude premium video content or new consumer/video records. To summarize, our findings remain consistent across multiple alternative experimental settings, which further demonstrates the advantages of our model and its tangible economic impact on the industrial platforms.

7 Conclusions

In this paper, we propose a novel multi-objective recommendation method DeepPRL presented in Figure 4 to highlight the importance of properly balancing between different objectives to improve their performance along the Pareto frontier and to provide satisfying recommendations accordingly. The backbone of the proposed DeepPRL method consists of two modules “Mixture of HyperNetwork” and “Deep Contextual Reinforcement Learning” (see Figure 4) that take into account the relationships between different objectives and determine the weight of each objective *in a personalized and contextualized manner*. For this reason, our method provides several technical novelties and leads to important modeling benefits in multi-objective recommendations that we have summarized in Section 4.5, including the following ones. First, it focuses on modeling complex relationships between different recommendation objectives in order to improve their performance simultaneously. This is achieved by modifying the existing HyperNetwork technique (Ha et al. 2016) into a multi-objective predicting network, where we incorporate a mixture-attention mechanism to model the heterogeneous objective relationships, leading to significantly better prediction performance. Second, it enhances the level of personalization and contextualization in multi-objective recommendations by selecting the appropriate set of objective weights for *each* consumer under *each* contextual scenario. This

is achieved by the Contextual Policy Gradient method that we developed in this paper, where we incorporate personalized and contextual information to determine the most suitable objective weights for recommendations. This method also tackles the problem of large action space commonly encountered in RL applications, enabling us to produce recommendations in an effective and efficient manner. Third, by utilizing deep learning and reinforcement learning techniques to build an end-to-end multiple objective recommendation framework, it mitigates the data sparsity and scalability problems in recommendations, since it is capable of automatically and effectively identifying consumer preference towards different objectives from archival records without requiring any explicit consumer feedback. Fourth, the utilization of the reinforcement learning technique also enables us to optimize the long-term (versus only the short-term) performance of multiple objective recommendations, which is crucial for the business success of the company in the long run. Finally, it is particularly flexible in the sense that it works for an arbitrary number of objectives. By updating the weight of each objective dynamically (vs. statically), it also manages to achieve significant improvements across *all* the objectives regardless of their relationships, without the need to sacrifice any performance metric.

These benefits, as well as theoretical properties that we discussed in Section 4.4, are empirically illustrated through offline experiments on three recommendation scenarios of Alibaba-Youku, Yelp, and Spotify, where our method significantly outperforms the state-of-the-art multi-objective recommendations baselines and dominates their Pareto frontiers. These improvements are substantial and significant across all the considered objectives without

enduring any “seesaw” phenomenon, illustrating that we do not need to sacrifice one performance metric to improve the performance of another, as they can be optimized and improved *simultaneously* by considering personalized and contextualized factors and adjusting recommendation policies accordingly. Our method also maximizes the performance for multiple objectives in the long-term, thus obtaining even greater performance improvements viz-a-viz existing solutions. To further demonstrate practical value of our method to the industry, we conducted a large-scale online controlled experiment at Alibaba-Youku, where our method achieved significant improvements over the latest production system across multiple conflicting business metrics in the long run, illustrating its tangible economic impact to the company.

As the future work, we plan to conduct additional experiments in other platforms and contexts to study the benefits of our method across different types of applications. We are also interested in exploring methods for producing constrained multi-objective recommendations.
