Submitted to ApJ

### ABSTRACT

In this study, galaxy samples have been generated using mock observation techniques based on the results of TNG100-1 simulations to investigate three forms of intrinsic alignment: satellite-central alignment between the orientation of the brightest group galaxies (BGG) and the spatial distribution of their satellites, radial alignment between the satellites' orientation and the direction towards their BGG, as well as direct alignment between the orientation of BGG and that of its satellites. Overall, the predictions of galaxy alignment generally align with observations, although minor discrepancies have been identified. For satellite-central alignment, the alignment strength and color-dependence trends are well replicated by the mock observations. Regarding radial alignment, the signals are weak but discernible, with no apparent color dependence. As for direct alignment, no signal is detected, nor is there any color dependence. We also investigate the alignment dependencies on halo or the BGG properties, and proximity effect. For satellite-central alignment, the predicted alignment signal shows a positive correlation with halo and BGG mass, consistent with observations and previous predictions. Similar correlations have also been observed with the BGG age and metallicity, which merit future observational analysis for confirmation. Proximity effects have been observed for all three types of alignment, with satellites closer to the BGG exhibiting stronger alignment signals. The influence of galaxy definition and shape determination on alignment studies is also analyzed. This study underscores the importance of employing mock observation techniques for a fair comparison between predictions and observations.

*Keywords:* galaxy: formation – galaxy: structure – methods: numerical – methods: observational – methods: statistical

### 1. INTRODUCTION

The hierarchical clustering model of galaxy formation, as proposed by White & Rees (1978) and further developed by subsequent studies (e.g., White & Frenk 1991; Lacey & Cole 1993; Ghigna et al. 2000; Dolag et al. 2009), suggests that galaxies form within dark matter halos through a process of hierarchical merging. This model posits that smaller halos merge to form larger ones, with the dense cores of smaller halos persisting as substructures within the larger halos, contributing to the complexity of galaxy assembly. The assembly histories of dark matter structures play a significant role

in determining the properties of galaxies, such as their color, size, metallicity, angular momentum, satellite number density, and spatial distribution. Understanding the connection between the assembly history of dark matter structures and the properties of galaxies is crucial for unraveling the mysteries of galaxy formation and evolution (e.g., Shen et al. 2003; Yang et al. 2005, 2006; Mo et al. 2010; Taylor et al. 2015; Wang & Kang 2018; Tang et al. 2020; Wang et al. 2021). Among these, the spatial distribution of galaxies can provide important clues to understand the merging history of dark matter structures (e.g., Faltenbacher et al. 2009; Li et al. 2013; Wang et al. 2020; Zhang et al. 2021) and the formation of galaxies (e.g., Faltenbacher et al. 2007; Agustsson & Brainerd 2010; Debattista et al. 2015).

Galaxy alignment is a critical tool for characterizing the anisotropy distribution of galaxy and has been the subject of

extensive research, with notable studies providing in-depth reviews on the topic (see, e.g., Joachimi et al. 2015; Kiessling et al. 2015, for review). Based on previous classifications (cf. Faltenbacher et al. 2007), there are primarily three distinct types of galaxy alignment observed within groups<sup>1</sup>: satellite-central alignment<sup>2</sup> between the orientation of the brightest group galaxies (BGG) and the distribution of its satellite galaxies, radial alignment between the orientation of a satellite galaxy and the direction toward its BGG, and direct alignment between the orientation of the BGG and that of its satellites.

The investigation on satellite-central alignment has been a topic of interest for several decades. In a historical context, Sastry (1968) found that there is a strong tendency for the major axis of the galaxy distribution to be orientated along the major axis of cD galaxies, while Holmberg (1969) reported that the satellites of local galaxies distribute peculiarly to the Galaxy disk. Since then, numerous studies have shown robust evidence of satellite-central alignment using large samples of galaxy surveys (e.g., Sales & Lambas 2004; Brainerd 2005; Agustsson & Brainerd 2006a; Weinmann et al. 2006; Yang et al. 2006; Faltenbacher et al. 2007; Wang et al. 2018; Rodriguez et al. 2022) and simulations (e.g., Kang et al. 2007; Faltenbacher et al. 2008; Bailin et al. 2008; Agustsson & Brainerd 2010; Bahl & Baumgardt 2014; Dong et al. 2014; Velliscig et al. 2015; Zhang & Wang 2019; Tang et al. 2020; Tenneti et al. 2021). It has indeed been demonstrated that satellite galaxies often align with the major axes of their central galaxies, and the strength of this alignment is affected by the color of the galaxies, with red galaxies showing stronger alignment signals compared to blue galaxies (e.g., Yang et al. 2006; Faltenbacher et al. 2007; Wang et al. 2018). Additionally, studies have revealed that the strength of satellite-central alignment also depends on the radial distance of satellite galaxies from the BGG. Specifically, galaxies located in the inner regions of clusters exhibit stronger alignment with the major axis of their BGG compared to galaxies in the outer regions (e.g., Faltenbacher et al. 2007; Dong et al. 2014).

While the phenomenon of satellite-central alignment has been established through various studies, there are discrepancies between theoretical predictions and observational findings. For instance, simulations often predict stronger satellite-central alignment compared to what is observed in actual data. Additionally, the predicted relationship between satellite-central alignment and galaxy color has not been ac-

curately replicated in observations (e.g., Kang et al. 2007; Wang et al. 2014). So far, most of the studies have focused on predicting the 3D alignment of halos rather than considering the 2D alignment that is relevant for observational comparisons. Additionally, lots of studies have defined Friends-of-Friends (FoF) groups as individual ‘galaxies’, which may not accurately represent the real galaxies in observations. These methodological limitations can contribute to the discrepancies observed between theoretical predictions and actual measurements of satellite-central alignment in galaxy clusters. Therefore, mock observations are highly demanded and have been practiced. For instance, the study by Tang et al. (2020) provides an example of how mock observations can help improve the alignment signal in galaxy clusters by constructing a mock galaxy sample from a Gadget-2 hydrodynamical simulation (Jing et al. 2006; Lin et al. 2006), Tang et al. (2020) were able to more accurately capture the distribution and properties of galaxies within clusters compared to previous studies that defined ‘galaxies’ as FoF stellar groups, such as Dong et al. (2014). However, as the galaxy colors in the simulations used by Tang et al. (2020) does not follow those of observations, the predicted color-dependence of satellite-central alignment can not fit with the observed one. Though it is indicated that a fair comparison between simulation predictions and observations must be made and state-of-the-art simulations are needed to better understand the nature of satellite-central alignment.

The initial observation of radial alignment was made by Hawley & Peebles (1975), highlighting the tendency for galaxies to be aligned in a radial manner within their host halos. Approximately 30 years later, using the galaxy catalog from the SDSS data, Agustsson & Brainerd (2006b) found significant evidence for radial alignment on scales of  $70 h^{-1} \text{kpc}$ , confirmed by Wang et al. (2019) using the SDSS DR13 data. In a study by Faltenbacher et al. (2007) a radial alignment signal was observed on distance scales of  $r < 0.7R_{\text{vir}}$  for red satellites within galaxy clusters. However, no significant radial alignment signal was found for blue satellites in the same study, suggesting a potential color dependence. Radial alignment signal has also been detected in other surveys. For example, Pereira & Kuhn (2005) found radial alignment in a sample of 85 X-ray-selected clusters, while Schneider et al. (2013) confirmed the existence of radial alignment signal by analyzing group catalog from the GAMA survey. Several studies have successfully reproduced the observed signal of radial alignment using numerical simulations (e.g., Knebe et al. 2008; Pereira et al. 2008; Rong et al. 2015; Knebe et al. 2020; Tenneti et al. 2021). For instance, by using a cosmological N-body simulation, Pereira et al. (2008) found a strong tendency for substructures to align radially with their host halos and suggested that tidal torque is the most plausible cause of the formation of ra-

<sup>1</sup> Here, groups actually include galaxy groups and clusters, introduced from the Friends-of-Friends clustering analysis.

<sup>2</sup> We will not adhere to the original term ‘halo alignment’ as used in Faltenbacher et al. (2007), but will refer to it as ‘satellite-central alignment’, as there is a difference in the orientation of the halo and the BGG.

dial alignment. Also using a cosmological N-body simulation, Knebe et al. (2008) found that, in the innermost region of galaxy clusters, the observed signal of radial alignment can be reproduced and independent of substructure mass. Lately, Knebe et al. (2020) represented the dependence of radial alignment signal on the distance to the center of the galaxy cluster and the dynamical state of galaxies by using hydrodynamical simulations.

The phenomena of direct alignment has just been revealed since this century. Plionis et al. (2003) analyzed a sample of 303 Abell clusters to show evidence of direct alignment in high-density environments, and found that the alignment signal is dependent on the velocity dispersion of the clusters. Ferrari et al. (2006) specifically reported that Abell 521 exhibited considerable red-sequence galaxy direct alignment out to about  $\sim 2 h^{-1}\text{Mpc}$  from the cluster core. However, subsequent studies have found that the direct alignment signal on the outer regions of clusters is absent. For example, Agustsson & Brainerd (2006b) showed that the signal of direct alignment is weak but noticeable on innermost scales of clusters, while no signal is observed on large scales (see also Mandelbaum et al. 2006). Faltenbacher et al. (2007) analyzed SDSS DR4 data and found a faint but significant indication for direct alignment on scales  $r < 0.1R_{\text{vir}}$  for red satellites, and subsequently verified by a  $\Lambda\text{CDM}$  N-body simulation (Faltenbacher et al. 2008). So far, the evidence for direct alignment and its dependence on galaxy properties are still controversial and need further investigation.

In this study, in order to make appropriate comparison between simulation predictions and observations, we utilize a mock galaxy sample constructed from the state-of-the-art TNG100-1 simulations to quantify signals for the three types of alignment and explore their dependence on galaxy or halo properties. The paper is organized as follows. Section 2 introduces the methodology, including the simulation data, mock sample construction, and definition of alignment. The main results will be presented in Section 3. Conclusions and discussion will be given in Section 4.

## 2. METHODOLOGY

### 2.1. simulations

The TNG100-1 simulations utilized here are provided by the Illustris-TNG Project <sup>3</sup> and described in Pillepich et al. (2018a), Springel et al. (2018), and Weinberger et al. (2017), while the public data release has been described in Nelson et al. (2019). These simulations incorporate a comprehensive model of gas physics and star formation, aiming to realize structure evolution from redshift  $z = 127$  to 0. The simulated cubic periodic box has a side length of  $75 h^{-1} \text{Mpc}$ , and

contains  $1820^3$  dark matter particles and the same number of gas particles, such that each dark matter and gas particle has a mass of  $7.5 \times 10^6 M_{\odot}$  and  $1.4 \times 10^6 M_{\odot}$ , respectively. A force softening length of  $0.74 h^{-1}\text{kpc}$  is adopted. The FoF algorithm (Davis et al. 1985) is used to identify dark matter halos and the SUBFIND algorithm (Springel et al. 2001) is employed to define substructures. The cosmological model for the simulations is the concordance  $\Lambda\text{CDM}$  model, with parameters adopted from Planck (Planck Collaboration et al. 2016), where  $\Omega_{\Lambda} = 0.6911$ ,  $\Omega_m = 0.3089$ ,  $\sigma_8 = 0.8159$ ,  $h = 0.6774$ .

### 2.2. construction of mock galaxy samples

The mock galaxy samples utilized in this study are sourced from Tang et al. (2021), and the galaxy definition is based on the Surface Brightness Limit Segmentation Procedure (SBLBP) algorithm, as detailed in Tang et al. (2020, 2021). The SBLBP algorithm comprises three main steps. Initially, the FoF groups of particles are projected onto x-y, y-z, and z-x planes to produce raw images, assuming a pixel size similar to that of the detector and convolved with a Moffat Point Spread Function (PSF) with parameters consistent with the typical seeing of the SDSS survey, as described by Moffat (1969). Subsequently, potential ‘galaxy’ candidates are identified based on a series of surface brightness thresholds that differentiate them from the background and diffuse stellar components. Finally, the third step involves reconstructing the galaxy samples following the procedure outlined in Tang et al. (2020) and elaborated in Tang et al. (2021). In essence, to replicate observations of galaxies, the SBLBP algorithm considers several factors, including the PSF, CCD pixel size, surface brightness threshold, redshift dimming, cosmological geometry effects, and dust extinction (Baes et al. 2011).

The utilization of these mock galaxy samples has enabled the successful reproduction of observed galaxy color bimodality, the galaxy star-forming rate (SFR) - stellar mass relationship, and the galaxy size dependence on stellar mass (Tang et al. 2021). Furthermore, the study by Tang et al. (2021) also predicted the galaxy stellar mass function and luminosity function, showcasing good agreement with observational data from studies such as Yang et al. (2009) and Bernardi et al. (2013), particularly at the massive or bright end of the galaxy population. This is in contrast to results derived from substructures by setting an upper limit of galaxy size with an arbitrary radius of  $30 h^{-1}\text{kpc}$ , as discussed by Pillepich et al. (2018b). Overall, these findings underscore the reliability of the mock observation techniques and highlight their potential for application in studying galaxy alignment phenomena.

The specific selection criteria for galaxy sample used in this study of alignment are as follows:

<sup>3</sup> <https://www.tng-project.org>

1. Surface brightness threshold: to compare with galaxy alignment study using SDSS data (e.g., Yang et al. 2006), a surface brightness threshold of  $25.0 \text{ mag arcsec}^{-2}$  in  $r$  band has been adopted to define galaxies in the simulation.
2. Redshifts: the galaxy groups are generated from snapshots for three redshifts ( $z \sim 0.01, 0.1$  and  $0.2$ ), to mimic SDSS galaxy redshift distribution.
3. Galaxy groups: only galaxy groups with a virial mass,  $M_{200}$ , greater than  $10^{12} h^{-1} M_{\odot}$  within a radius of 200 times the mean density of the universe are included.
4. Central and satellite Galaxies: only centrals and satellites with stellar mass greater than  $1.4 \times 10^8 h^{-1} M_{\odot}$  (more than 200 particles) and semi-major axes longer than  $2.96 h^{-1} \text{kpc}$  (4 times of the softening length) are included in the samples, to alleviate resolution effect. Here the central galaxy is defined as the brightest group galaxy (BGG).
5. Apparent magnitude: the galaxies of interest are limited to have an apparent magnitude,  $m_r$ , brighter than 17.77 mag in the SDSS- $r$  band (cf. Yang et al. 2006).

Applying the above selection criteria, we extracted in total 12,987 ‘satellite-BGG’ pairs from the mock galaxy samples. The sample of these pairs will be referred as ‘mock sample’ in the following studies. To compare with previous studies, we also analyze the spatial distribution of substructures defined by SUBFIND algorithm applying the same criteria.

### 2.3. definition of galaxy alignment

Figure 1 illustrates three types of satellite alignment related to their host BGGs, where the solid lines with arrows represent the major axes of the satellite galaxy (yellow) and BGG (red). To calculate the shape of galaxy or substructure and determine the major axis, two methods will be applied. In ‘Method-mock’, the ellipticity of the mock galaxy is determined by analyzing its image and fitting ellipses to the isophotes. This method leverages the brightness contours to extract the major axis direction of the galaxy, providing valuable information on its shape and orientation. On the other hand, ‘Method-sub’ focuses on the 2D shape of substructures by calculating the moments of inertia of the stellar mass distribution. By computing the principal axes of the inertia tensor, the major axis direction of the substructure can be identified. This approach offers insights into the intrinsic structure and alignment of substructures within the galaxy system. The inertia tensor,  $I_{i,j} = \sum_{k=1}^N x_{i,k} x_{j,k} m_k / \sum_k m_k$ , where  $x_{i,k}$  and  $x_{j,k}$  are the distance of  $k$ th particle from the subhalo center in  $i$  and  $j$ -dimension respectively, and  $m_k$  is the mass of  $k$ th particle. Here,  $N$  is the particle number of the stellar substructures. By summing over the particle masses and

distances, the inertia tensor provides a quantitative measure of the mass distribution and enables the determination of the major axis direction.

In Figure 1, BGG is placed on the coordinate origin, and  $\theta$ ,  $\varphi$  and  $\xi$  are indicators for satellite-central, radial and direct alignment, respectively. This is also illustrated in Figure 1 of Faltenbacher et al. (2007) and Kiessling et al. (2015). In the context of satellite-central alignment, a significant alignment signal is indicated by a distribution of small angles or an average angle  $\langle \theta \rangle < 45^\circ$ . This suggests that satellite galaxies tend to be preferentially distributed along the major axis of the central galaxy. The strength of the alignment signal is quantified by the average angle, with smaller average values indicating a stronger alignment signal. Similar concepts apply to radial and direct alignment signals, which are characterized by the average angles  $\langle \varphi \rangle$  and  $\langle \xi \rangle$ , respectively. In the absence of any alignment, the average angle would be  $45^\circ$ . However, it is important to note that an average angle of  $45^\circ$  does not necessarily imply an isotropic distribution of satellite galaxies around central galaxies.

**Figure 1.** The illustration of three types of alignment and the representing angles between the BGGs and satellites (or substructures). The solid lines with arrows represent the major axes of the satellite galaxy (yellow) and BGG (red). The long-dashed line connects the centers of the satellite and the BGG, while the dotted line is parallel to the major axis of the BGG. Here,  $\theta$ ,  $\varphi$  and  $\xi$  denote the satellite-central, radial, and direct alignments, respectively.

## 3. RESULTS

In this section, results for the three types of alignment and their dependence on galaxy or halo properties, including galaxy color, halo mass, stellar mass, age and metallicity, as well as the distance from the BGG, will be given. To quantify the strength of alignment signal, a normalized number density distribution is utilized. The normalized number density distribution provides a measure of the relative density of aligned galaxies, taking into account variations in galaxy number counts. It is computed by dividing the number of galaxy pairs within a specific angle range by the same num-

ber in a random sample, as following,

$$P(\text{angle}) = \frac{N(\text{angle})}{\langle N_r(\text{angle}) \rangle} \quad (1)$$

where  $N(\text{angle})$  is the count of satellite galaxies in  $\text{angle}$  bins, while  $\langle N_r(\text{angle}) \rangle$  is the average count of random samples in the same bins. This calculation considers the area or volume covered by each measurement, ensuring that the distribution accounts for the spatial coverage.  $P(\text{angle}) = 1$  means the isotropic distribution, while  $P(\text{angle}) > 1$  at any  $\text{angle}$  implies a distribution with preferred alignment.

### 3.1. alignment for the whole samples

The predictions of satellite-central, radial, and direct alignment from the mock sample and stellar substructures, are plotted as the red long-dashed and green solid lines in Figure 2. Observational results from SDSS data (Pereira & Kuhn 2005; Yang et al. 2006; Wang et al. 2018; Rodriguez et al. 2022), and the prediction from Gadget-2 simulation (Tang et al. 2020), are also shown for comparison.

In Figure 2, it is evident that the stellar substructures exhibit prominent alignment signals across all three types, with a particularly notable strength in radial alignment. These predicted alignment signals surpass those observed in real data and in predictions from the mock sample, thus confirming and reinforcing earlier findings (Tang et al. 2020).

The left panel of Figure 2 illustrates results for satellite-central alignment. The normalized probability distribution of satellite-central alignment angles for the mock sample, represented by the red long-dashed line with filled diamond, closely matches the observations with only a small difference. The average angle for the mock sample ( $\langle \theta \rangle_{\text{mock}} = 41.6 \pm 0.2^\circ$ ) is marginally larger than a previous prediction of  $41.0 \pm 0.6^\circ$  (Tang et al. 2020), and is approaching the observational results, specifically  $42.2 \pm 0.2^\circ$  (Yang et al. 2006) and  $42.4 \pm 0.6^\circ$  (Rodriguez et al. 2022).

The middle panel of Figure 2 displays the findings for radial alignment. The red long-dashed line indicates the results for the mock sample, while the observational results for various SDSS galaxy samples (Pereira & Kuhn 2005) are depicted by three black solid lines with distinct symbols. The plot reveals that our predictions show a modest yet noticeable radial alignment, with an average angle of  $\langle \varphi \rangle_{\text{mock}} = 44.3 \pm 0.2^\circ$ . There are tendencies towards excess or deficiency in small or large angles, respectively, broadly consistent with the observational outcomes for galaxies in clusters (Pereira & Kuhn 2005), namely  $42.8 \pm 0.6^\circ$  for a spectroscopic sample ('Sample A') and  $43.9 \pm 0.4^\circ$  for a photometric sample ('Sample B').

In the right panel of Figure 2, the outcomes for direct alignment are represented. As there are no observational data points available for this plot, we solely rely on the results from the mock sample. The findings suggest an almost

isotropic distribution between the orientation of the BGG and those of satellites. Specifically, we find that  $\langle \xi \rangle_{\text{mock}} = 44.9 \pm 0.2^\circ$ , with  $P(\xi) \sim 1$ . This means that there is little direct alignment between the central and satellite galaxies in our mock sample, indicating a random distribution of orientations.

### 3.2. dependence on galaxy or halo properties

In further analysis, we delve deeper into exploring the relationship between galaxy alignment and various properties of mock galaxies or halos, including galaxy color, halo mass, BGG stellar mass/age/metallicity, as well as the radial distance of satellites toward the BGG. By examining how galaxy alignment may vary with these diverse characteristics, we aim to uncover the underlying mechanisms that drive galaxy alignments.

#### 3.2.1. galaxy color

The galaxy color is defined as  $^{0.1}(g-r)$ , which represents the  $(g-r)$  color k-corrected to a redshift of  $z = 0.1$ . This color is calculated using the formula  $^{0.1}(g-r) = 0.7188 + 1.3197[(g-r) - 0.6102]$ , as detailed in Blanton & Roweis (2007). For the star particles within the galaxies, their magnitudes is computed in each band using the simple stellar population model by Bruzual & Charlot (2003).

In this approach, we will divide the mock galaxy sample into red and blue categories based on the  $^{0.1}(g-r)$  color criterion of 0.7. This choice is motivated by the need to accurately classify galaxies in the high mass range, as the fitting line used in previous studies (e.g., Tang et al. 2020) may misclassify a significant fraction of high-mass mock galaxies as blue. The decision to use 0.7 instead of 0.83, the value adopted in (Yang et al. 2006), is supported by the color bimodality observed in TNG100 simulations. The distribution of galaxy colors in TNG100 simulations, as shown in Figure 3 of Nelson et al. (2017), reveals a dip between the two peaks of the color distribution around  $\sim 0.6$  in  $(g-r)$  color, which corresponds to approximately  $^{0.1}(g-r) \sim 0.7$ . Furthermore, the stellar mass-color map derived from our mock sample (refer to the left panel of Figure 3 in Tang et al. (2021)) demonstrates that the horizontal line at  $^{0.1}(g-r) = 0.7$  effectively separates the red and blue clouds in our simulated data. This criterion provides a clear distinction between red and blue galaxies in our sample, aligning with the color classification used in previous studies by Yang et al. (2006) and Wang et al. (2018), which serve as the main comparative targets for our analysis. Other color thresholds, such as  $^{0.1}(g-r)$  values of 0.73 and 0.76, were tested, but they did not significantly impact the alignment predictions. Additionally, galaxies with  $\log_{10}(M/h^{-2}M_\odot) > 11.5$  were classified as red galaxies to align with the SDSS survey's distribution of spiral galaxies (Xiaohu Yang, private communication). This classification did not notably affect the predictions.

**Figure 2.** Results for the three types of alignment, i.e., satellite-central, radial, and direct alignment, are plotted in the left, middle, and right panels, respectively. In all panels, the red long-dashed line with filled diamond represent results for the mock galaxy sample from TNG100-1 simulation, while the green solid lines with open circle represent results for stellar substructures. The error bars are computed by  $\sigma_{r(\text{rangle})}/N_{r(\text{angle})}$ , where  $\sigma_{r(\text{rangle})}$  is the standard deviation of  $N_{r(\text{angle})}$  obtained from the 100 random samples. The legends in each panel provide average values for  $\langle \theta \rangle$ ,  $\langle \varphi \rangle$ , and  $\langle \xi \rangle$  with  $1\sigma$  standard deviation, while the subscript ‘mock’ and ‘sub’ refer to results derived by ‘method-mock’ and ‘method-sub’ respectively. Left Panel: results for satellite-central alignment. The dotted-dash line with open triangle, the solid line with open triangle, and the blue solid line with filled diamond, represent results for the mock galaxies from Gadget-2 simulation (Tang et al. 2020), observational results from SDSS DR2 (Yang et al. 2006), and SDSS DR16 (Rodríguez et al. 2022), respectively. In this plot, the result derived from SDSS DR7 (Wang et al. 2018) is also listed. Middle Panel: results for radial alignment. The other three solid lines with triangle, open circle and filled circle are for observational results from three different samples (Pereira & Kuhn 2005). Note that the result denoted as ‘PereiraC’ represents an isotropic orientation of satellite galaxies for a control sample, with null alignment signal. Right Panel: results for direct alignment.

The mock sample, consisting of satellite-BGG pairs, was then divided into four color-based subgroups: red satellite-BGG pairs, blue satellite-BGG pairs, red BGG-satellite pairs, and blue BGG-satellite pairs, labeled as ‘Red Satellites’, ‘Blue Satellites’, ‘Red Centrals’, and ‘Blue Centrals’, respectively. The number distribution of these pairs is presented in Table 1. These subgroups are referred to as single-color subgroups, as they are based on the colors of either centrals or satellites. Similarly, four subgroups of substructure-BGG pairs were also created using the same method for comparison.

The results for color dependence are displayed in Figure 3. The panels are organized from top to bottom for satellite-central alignment, radial alignment, and direct alignment, respectively. The columns from left to right represent the four subsamples, as denoted in the lower corner of each panel. The symbols, lines, and annotations used in the figure are consistent with those in Figure 2. Upon initial inspection, it is evident that the alignment signals for substructures (represented by the green solid lines) are notably stronger than those for the single-color subgroups, akin to the trends observed in Figure 2.

As indicated in the legends of the top panels, our predicted average satellite-central alignment angles for ‘Red Satellites’ and ‘Red Centrals’ ( $40.8 \pm 0.3^\circ/41.2 \pm 0.3^\circ$ ) are a bit smaller than the values derived from observational data, specifically  $41.5 \pm 0.3^\circ/41.5 \pm 0.2^\circ$  (Yang et al. 2006) and  $42.0 \pm 0.6^\circ/42.2 \pm 0.6^\circ$  (Rodríguez et al. 2022). However,

the lines representing predictions and observations for red subsamples are nearly indistinguishable, indicating a high level of agreement. On the other hand, the predicted average angles for blue subsamples, particularly ‘Blue Centrals’, remain notably smaller compared to the observed values, with our prediction of  $43.1 \pm 0.5^\circ$ , contrasting with the observed values of  $44.5 \pm 0.5^\circ$  (Yang et al. 2006) and  $45.8 \pm 0.6^\circ$  (Rodríguez et al. 2022). The contrasting trends in color dependence predictions between our current study and the previous work by Tang et al. (2020) are indeed intriguing. The present predicted satellite-central alignment strengths for ‘Red Satellites’, ‘Red Centrals’, ‘Blue Satellites’, and ‘Blue Centrals’ exhibit a clear trend from strong to weak, which aligns well with the observed color dependence trend reported in Yang et al. (2006) and Rodríguez et al. (2022). This is the first time that the observed color-dependence of satellite-central alignment has been recovered properly by predictions. This consistency further validates our predictions and highlights the importance of using advanced algorithms and simulations for studying galaxy satellite-central alignment.

The middle panels of the analysis show that the radial alignment signals for all mock subsamples are indeed weak but noticeable. There is a tendency for excessive or deficient alignment at small or large angles, with average angles of  $44.4 \pm 0.3^\circ/44.3 \pm 0.3^\circ$  for the ‘Red Satellites’ and ‘Red Centrals’ subsamples and  $44.3 \pm 0.3^\circ/44.4 \pm 0.5^\circ$  for the ‘Blue Satellites’ and ‘Blue Centrals’ subsamples, respectively. These results indicate that there is a consistent but

subtle radial alignment signal present across different subsamples, regardless of galaxy color. The obvious variations in the average angles for different color subsamples of substructures implies suggest that there might be some differences in the alignment patterns between red and blue counterparts, although the overall alignment signals for mock subsamples remain weak.

The analysis of direct alignment in the bottom panels reveals no distinct signal predicted from any of the single-color subgroups. This is evidenced by the almost flat curves in the normalized probability distribution, with  $P(\xi)$  remaining approximately constant at 1, and the average alignment angle  $\langle \xi \rangle$  hovering around  $45^\circ$ . However, the color subsamples for substructures have shown significant direct alignment signals.

The analysis conducted by Yang et al. (2006) highlights the importance of considering the color properties of both central and satellite galaxies within a halo, particularly due to the observed ‘galactic-conformity’ phenomenon where the color of satellites tends to be correlated with the color of the central galaxy in the same halo (e.g., Weinmann et al. 2006). To further explore this color dependence, the mock sample can be divided into double-color subsamples based on the colors of both central and satellite galaxies. For example, a subsample with red central galaxies and red satellites would be referred to as the red-red subsample, following the convention of naming subsamples based on the colors of centrals and satellites. By creating these double-color subsamples, it becomes possible to investigate how the color properties of both centrals and satellites within a halo influence galaxy alignments and orientations. The numbers of pairs for these double-color subsamples can be found in Table 1.

The results presented in the left two columns of panels in Figure 4 show a comparison between the predictions for satellite-central alignment from different double-color subsamples and the observational results from Figure 4 in Yang et al. (2006) (refer to the average angles labeled ‘Yang’). Interestingly, the predictions from the red-red, red-blue, and blue-red subsamples exhibit a good agreement with the observational data. The prediction from the blue-red subsample ( $\langle \theta \rangle_{mock} = 43.9 \pm 0.8^\circ$ ) closely matches the observed value of  $44.8 \pm 0.7^\circ$ . This is surprising, considering the apparent inconsistency illustrated in the top-right panel of Figure 3 for ‘Blue Centrals’. On the other hand, for the blue-blue subsample, the predicted alignment angle ( $\langle \theta \rangle_{mock} = 42.4 \pm 0.7^\circ$ ) deviates significantly from the observational result ( $44.2 \pm 0.6^\circ$ ). These results indicate that the discrepancy between our predictions and observations is minimal and is mainly caused by the excessive anisotropic distribution of blue satellites around blue central galaxies in the simulations, which is the same reason for the too strong alignment signal found in Tang et al. (2021).

Using the same subsamples, we also predict color dependence for radial and direct alignment, with results shown in the other four columns of the panels. For radial alignment, only the blue-blue subsamples exhibit strong alignment signals, while the other three double-color subsamples show no significant alignment. In contrast, direct alignment shows almost no color dependence, as illustrated in the right panel of Figure 4.

Finally, it should be noted that predictions from the double-color subsamples can be used to infer those from single-color subsamples.

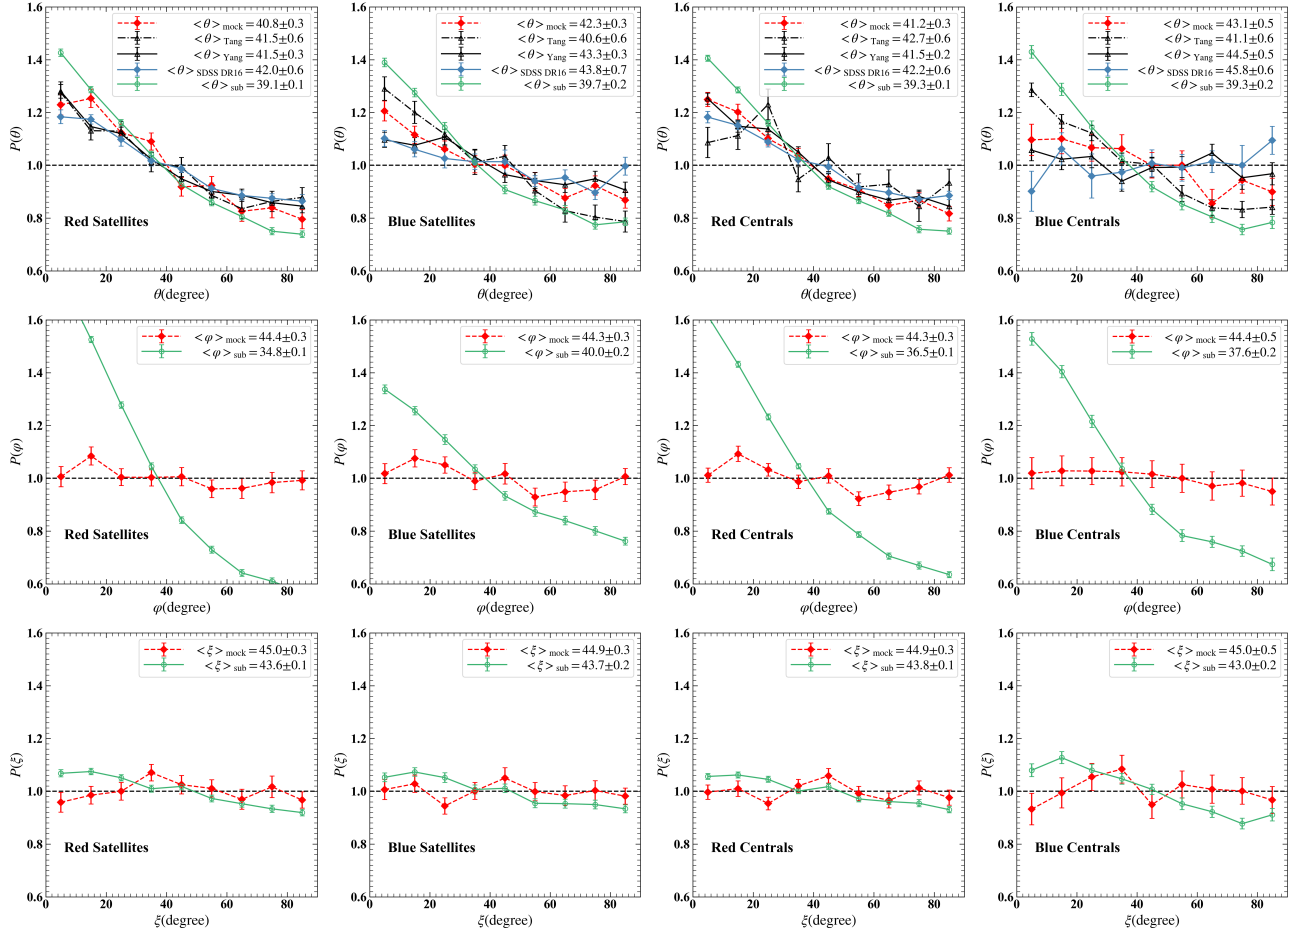

### 3.2.2. halo mass and BGG mass

There have been evidences that the alignment signal increases with the mass of host halos and BGGs (e.g., Yang et al. 2006; Dong et al. 2014; Brainerd & Yamamoto 2019). Figure 5 and Figure 6 have been drawn to reproduce this dependency.

The panels in Figure 5 display the average angles  $\langle \theta \rangle$ ,  $\langle \varphi \rangle$ , and  $\langle \xi \rangle$  as functions of the mass of the dark matter halo within a radius of 200 times the mean density of the universe,  $M_{200}$ . The lines represent results for the entire mock sample and the four color subsamples, as indicated in the legends.

The left panels of Figure 5 indicate that for the blue subsamples (‘Blue Satellites’ and ‘Blue Centrals’),  $\langle \theta \rangle$  hovers around  $43^\circ$ , while the alignment strengths of the entire sample (‘All’, the same in the following) and the red subsamples (‘Red Satellites’ and ‘Red Centrals’) show a positive correlation with halo mass. This halo mass dependence trend, particularly evident for the entire sample, is consistent with previous predictions (e.g., Dong et al. 2014; Wang et al. 2018) and observational findings (see, e.g., Figure 5 in Yang et al. 2006). The pattern of the radial alignment signal variation with halo mass appears somewhat complex, as depicted in the middle column of panels. It seems that galaxy pairs within less massive halos exhibit a stronger radial alignment signal compared to those in more massive halos, with the exception of the ‘Red Satellites’ subsample, which displays large error bars and fluctuations. This alignment trend aligns with the concept that radial alignment may arise from BGG and satellite interactions, which are more pronounced in relatively small mass halos. As illustrated in the right column of panels, the average direct alignment angles  $\langle \xi \rangle$  exhibit a comparable trend of mass dependence to  $\langle \varphi \rangle$ , albeit with generally weaker alignment signals on average.

The dependence of alignment on the stellar mass of central galaxies has been investigated and is presented in Figure 6. Similar to Figure 5, the satellite-BGG pairs have been grouped into four mass bins based on the range of BGG mass. The settings for points, lines, colors, and legends are

**Figure 3.** Same as Figure 2, but for subsamples with different colors. The panels in row from top to bottom are for satellite-central, radial and direct alignment respectively, while the panels in the column from left to right are for ‘Red Satellites’, ‘Blue Satellites’, ‘Red Centrals’, ‘Blue Centrals’ subsample, respectively.

**Figure 4.** Same as Figure 2, except that here the mock sample has been split further according to the colors of both the central and the satellite galaxies, as indicated in the low-left corner of each panel. The panels in the column from left to right represent satellite-central, radial and direct alignment, respectively.

the same as those in Figure 5. Unsurprisingly, the dependencies on BGG mass for the three types of alignment exhibit similarities to those in Figure 5, considering the relationship

between BGG mass and halo virial mass in this mass regime, i.e.,  $\geq 10^{12} M_{\odot}$  (e.g., Nelson et al. 2019; Tang et al. 2021).

**Table 1.** Number of galaxy pairs for color subsamples

Type of subsamples	Red Satellites	Blue Satellites	Red Centrals	Blue Centrals
number of pairs	6,243	6,744	10,338	2,649
Type of subsamples	red-red	red-blue	blue-red	blue-blue
number of pairs	5,130	5,208	1,113	1,536

The strengths of radial and direct alignment appear to be more pronounced at the lower end of the mass range. The intricate patterns observed in the relationship between radial and direct alignment and halo/BGG mass are likely influenced by various factors, such as the dynamical state of satellites within host halos. Further exploration and analysis are necessary to fully understand and clarify the underlying reasons for these trends. Factors such as the assembly history of halos, environmental influences, and the specific mechanisms driving alignment signals in different mass regimes may all contribute to these complexities.

### 3.2.3. BGG age and metallicity

The metallicity and age of galaxies are determined by averaging these properties over all the star particles within the constructed ‘galaxy’. It’s important to note that the metallicity for star particles is obtained from the TNG100-1 snapshots, while the age is calculated based on the formation epoch of the star particles. To analyze the dependency of alignment on galaxy age and metallicity, similarly the satellite-BGG pairs will be divided into four consecutive bins with different ranges of BGG age or metallicity. The results are presented in Figure 7 and Figure 8 for age and metallicity dependence, respectively.

As shown in Figure 7, on average, for the entire mock sample, the predicted satellite-central alignment strengths exhibit positive correlations with BGG ages. In contrast, the radial and direct alignment strengths show very weak correlations and complex patterns of dependence. Specifically, for satellite-central alignment in the left-hand side column panels, the blue subsamples demonstrate a complex dependency of alignment on BGG ages, whereas the satellite-central alignment strengths for the red subsamples are positively correlated with BGG ages, particularly for the ‘Red Satellites’ subsample. However, in the radial/direct alignment analysis shown in the middle/right-hand side column panels respectively, the dependence on BGG ages exhibits a high degree of scatter, and no clear trend can be discerned. In addition, for all three types of alignments, we can see that the BGG age dependence trend of the entire mock sample well align with ‘Blue Centrals’ in small age end and ‘Red Centrals’ in large age end, respectively. This is because when

large age region central galaxies are dominated by red galaxies, and vice versa.

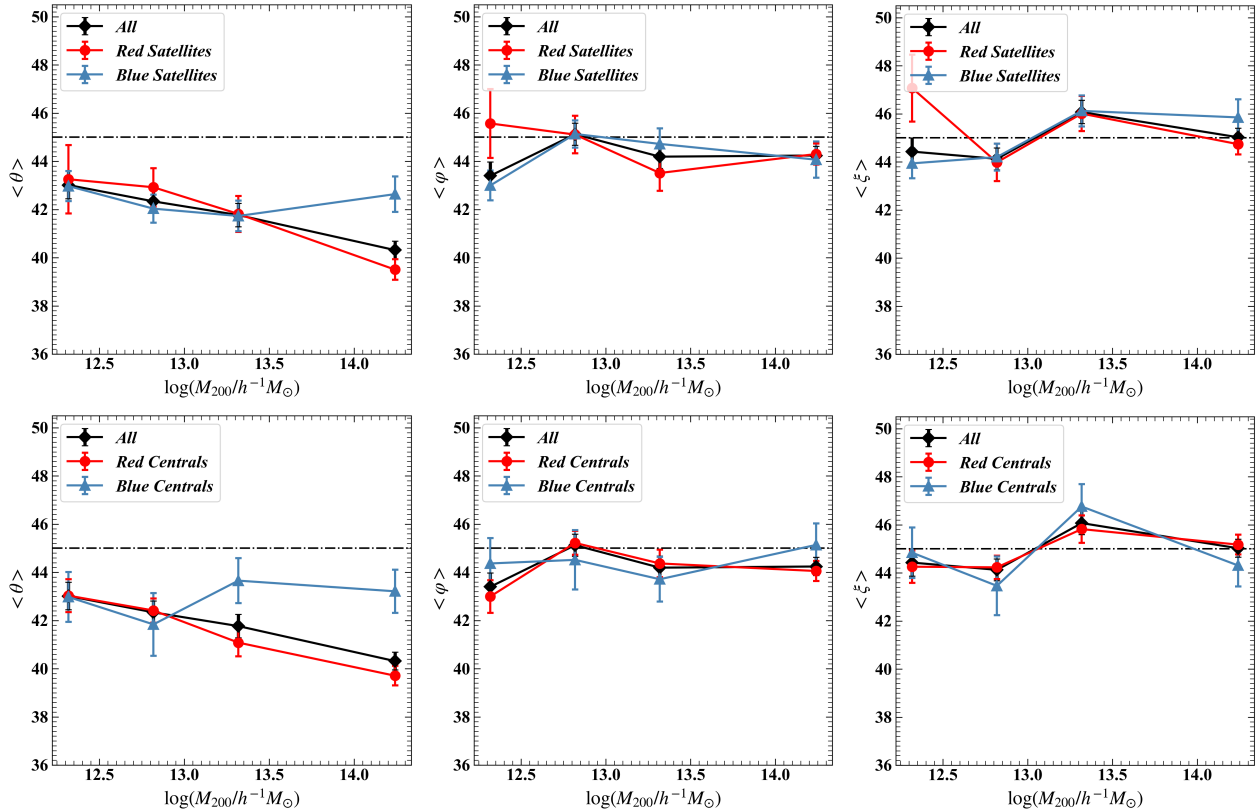

Figure 8 shows the correlation between alignment and BGG metallicity. The findings suggest that satellite-central alignment patterns resemble those observed with BGG age dependence. Specifically, halos with metal-rich BGGs exhibit more pronounced BGG-satellite alignment compared to those with metal-poor BGGs. This is consistent with the dependence on halo mass or BGG mass, as mass and metallicity are correlated.

Overall, the results exhibit significant scatter in terms of age, and metallicity dependence, especially for the blue subsamples, indicating a complex relationship between alignment strength and the properties of BGGs. However, it is crucial to acknowledge that some data points in these plots may lack statistical significance due to the limited number of blue galaxy pairs with old age or high metallicity, and vice versa for red galaxy pairs. To improve statistical robustness, a larger mock sample is required for further analysis.

### 3.2.4. radial distance

The dependency of alignment strength on the satellite centric distance from the BGG center has been extensively studied in the literature (e.g., Agustsson & Brainerd 2006b; Yang et al. 2006; Faltenbacher et al. 2007; Dong et al. 2014; Tang et al. 2020). In this study, further investigation was conducted using the mock sample to examine this relationship. The average angles for satellite-central, radial, and direct alignment as functions of satellite projected radial distance are shown in the left, middle, and right panels of Figure 9, respectively. The projected distances are normalized by the virial radius of the host dark matter halos, and the center of the dark matter halo is calculated by summing the mass-weighted relative coordinates for all types of particles in the FoF group.

The analysis of Figure 9 reveals that, in general, for the entire mock sample and most of the color subsamples (except for the blue-red subsample), all three types of alignment exhibit a clear radial dependence. Specifically, galaxies located closer to the center of their BGG exhibit stronger alignment compared to those located further away, consistent with previous observational studies (Faltenbacher et al. 2007). However, the radial dependence for the blue-red subsample appears to differ from the other subsamples, exhibiting abnor-

**Figure 5.** The average angle  $\langle \theta \rangle$ ,  $\langle \varphi \rangle$  and  $\langle \xi \rangle$  as a function of the mass of dark matter halo. The panels in each row, from top to bottom, represent satellites single-color (‘Red Satellites’, ‘Blue Satellites’) and centrals single-color (‘Red Centrals’, ‘Blue Centrals’) subsample, respectively. The panels in each column, from left to right, correspond to satellite-central alignment, radial alignment, and direct alignment, respectively.

mal behavior. This discrepancy warrants further investigation to understand the underlying mechanisms driving the alignment patterns observed in this specific color subsample.

In addition, our simulation results highlight the strong significance of satellite-central alignment signals for all satellite galaxies within the entire halo, whereas both radial and direct alignments are particularly noticeable at scales where the projected separation  $r_p \lesssim 0.2R_{vir}$ . The results of radial dependence for satellite-central alignment are in broad agreement with observations (Yang et al. 2006; Faltenbacher et al. 2007) and previous simulation predictions (Dong et al. 2014).

In terms of radial alignment, our predictions show discrepancies compared to the observational findings presented in Figure 3 of Faltenbacher et al. (2007). The alignment in the ‘Blue Satellites’ subsample appears to be more significant than in the ‘Red Satellites’ subsample, contrary to the observational results. Additionally, while the observational conclusion indicates significant signals for red satellites at scales  $r_p < 0.7R_{vir}$ , our predictions reveal significant alignment signals for both red and blue satellites, but only at small projected separations.

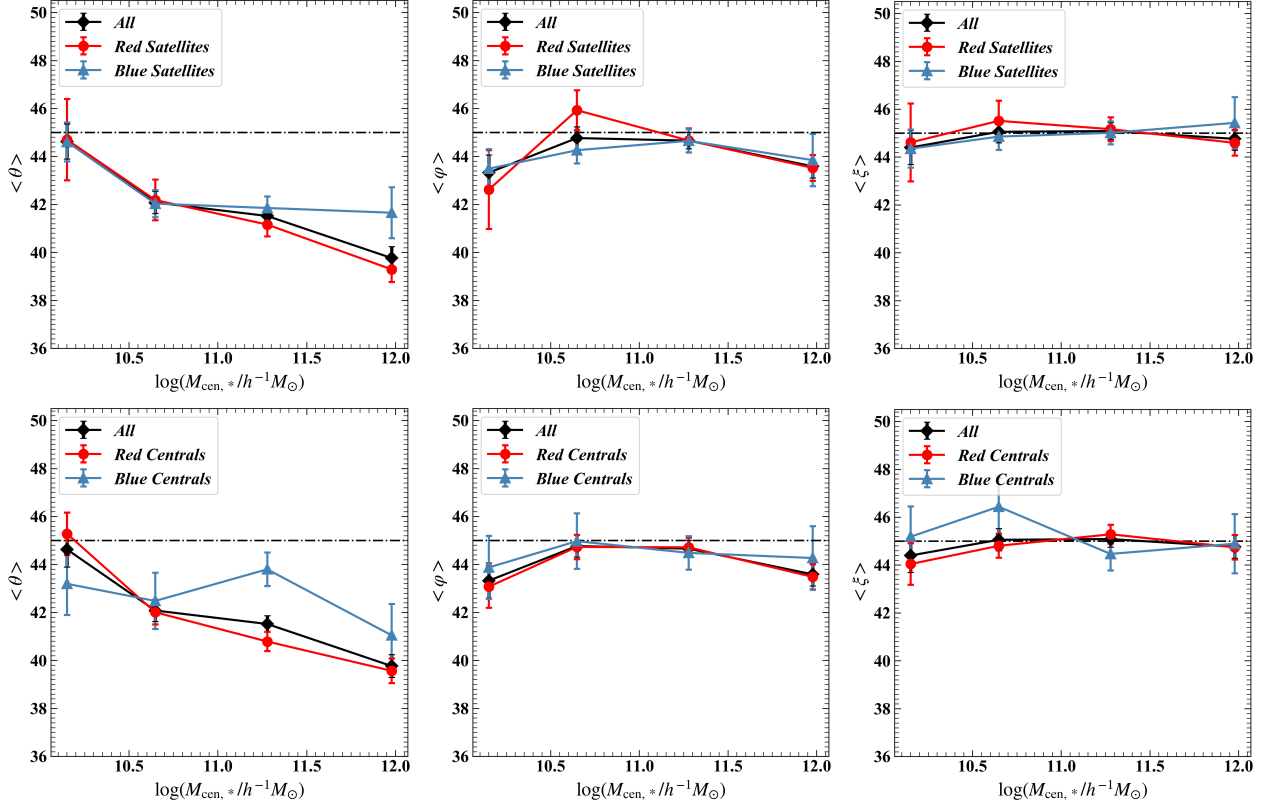

For direct alignment, our predictions are consistent with the observational results on scales where the projected separation  $r_p < 0.1R_{vir}$  (as reported in Faltenbacher et al. 2007).

Interestingly, it has been observed that the ‘blue-blue’ subsample consistently exhibits the most significant proximity effect among all three types of alignment.

It is important to note that due to the relatively small size of our mock sample, we did not divide the satellite galaxies into red, green, and blue subsamples as done in the observational study by Faltenbacher et al. (2007). As a result, caution is advised when interpreting the comparison results above.

### 3.3. the influence of surface brightness thresholds

Galaxies in observations are typically defined by the faintest detectable edge determined by the surface brightness depths of surveys like 2dFGRS (Folkes et al. 1999), SDSS (York et al. 2000), and DESI (DESI Collaboration et al. 2016), etc. The shape and orientation of galaxies can vary significantly with different surface brightness contours, leading to the ‘isophote twist’ phenomenon observed in elliptical (e.g., Fasano & Bonoli 1989; Nieto et al. 1992; Huang et al. 2013) and spiral galaxies (e.g., Gong et al. 2023). To ensure a fair comparison with observational results, it is crucial to use the same surface brightness threshold to define mock galaxies

**Figure 6.** Same as Figure 5, but for the dependence on BGG mass.

in simulations. We chose a threshold of  $25.0 \text{ mag arcsec}^{-2}$  in the  $r$  band to align with SDSS data (Yang et al. 2006; Faltenbacher et al. 2007). Exploring the influence of surface brightness thresholds on alignment predictions could be a worthwhile research avenue.

The orientation of the Brightest Group Galaxy can be characterized by the position angle (PA) of its major axis. In our analysis, we calculate the absolute value of the relative PA difference,  $DPA = |\alpha_{28.5} - \alpha|$ , where  $\alpha_{28.5}$  represents the PA of the BGG defined with a surface brightness threshold of  $\mu_r = 28.5 \text{ mag arcsec}^{-2}$ . We have plotted the variation of  $DPA$  with different surface brightness thresholds in Figure 10. In the figure, the black solid lines represent all BGGs, while the other lines correspond to results categorized by halo mass (left panel) and stellar mass (right panel) in various mass ranges, as indicated in the legends. This analysis allows us to study how the orientation of BGGs changes with different surface brightness thresholds and how it depends on the properties of the halos and stellar masses.

The analysis of Figure 10 reveals some key trends regarding the variation of  $DPA$  with different surface brightness thresholds and the properties of halo and stellar mass. We observe that  $DPA$  increases significantly with a brighter threshold,  $\mu_{r,\text{limit}}$ , and can reach values up to  $\sim 40^\circ$ . This suggests that the orientation of BGGs is highly sensitive to the surface brightness threshold used in defining their major

axis. Furthermore, we find that the average  $DPA$  for BGGs in less massive halos is larger compared to those in more massive halos. This difference can be attributed to the fact that low-mass BGGs are more likely to be spiral galaxies, while high-mass BGGs tend to be elliptical galaxies. Spiral galaxies typically exhibit larger angular momentum and distinctive arm structures, leading to a more pronounced rotation pattern compared to elliptical galaxies.

The variation trend of  $DPA$  with BGG stellar mass parallels that of halo mass, given the direct correlation between BGG mass and halo mass. These findings emphasize the necessity of meticulously selecting the surface brightness threshold when determining BGG orientations, particularly in comparisons with observational data. Considering these trends enables researchers to more accurately interpret and analyze the orientation properties of BGGs in galaxy clusters.

Furthermore, as the surface brightness thresholds for defining galaxies become dimmer, the alignment signals tend to strengthen, as shown in Table 2. This is because dimmer thresholds encompass more peripheral regions, potentially including tidal tails or wrapped structures, which leads to varied orientations and stronger alignment signals. Notably, as the alignment signals for galaxies with fainter thresholds strengthen, they approach those for stellar substructures (see results in Figure 2), indicating a closer morphological match.

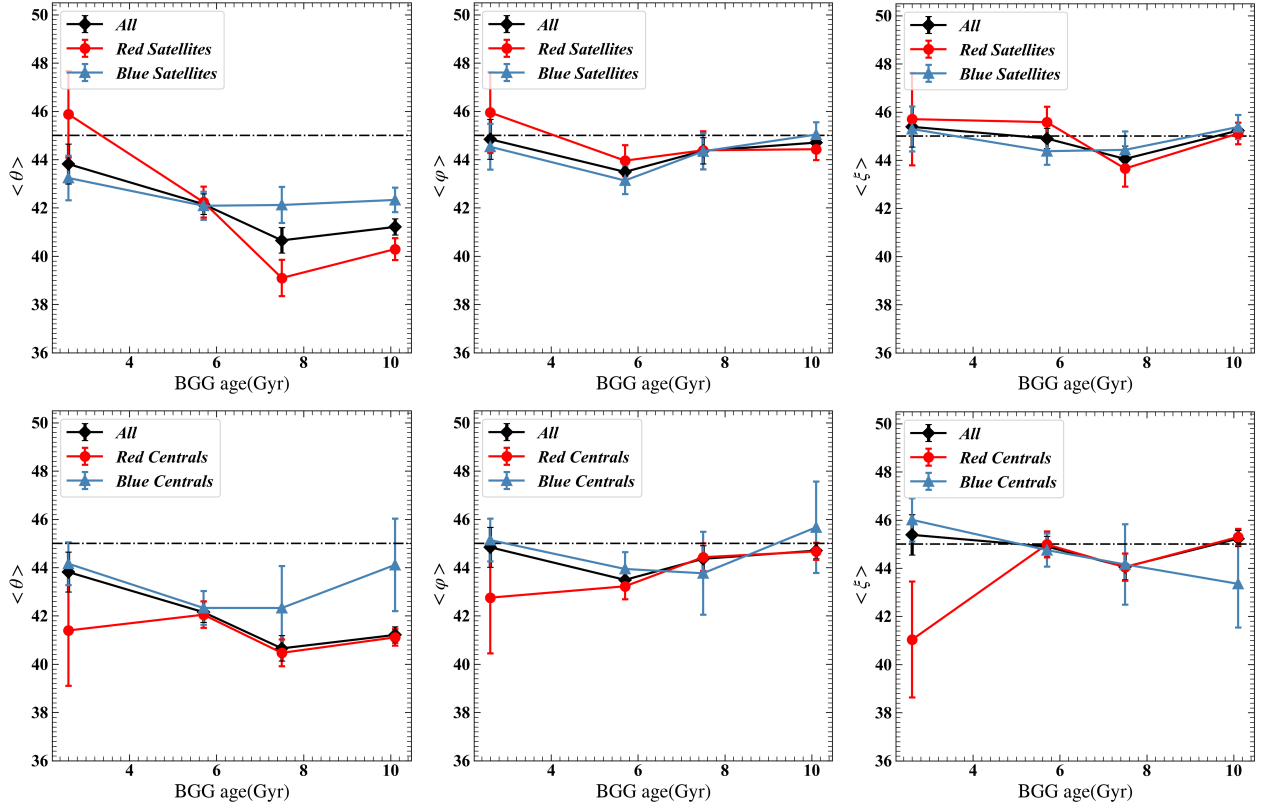

Figure 7. Same as Figure 5, but for the dependence on BGG age.

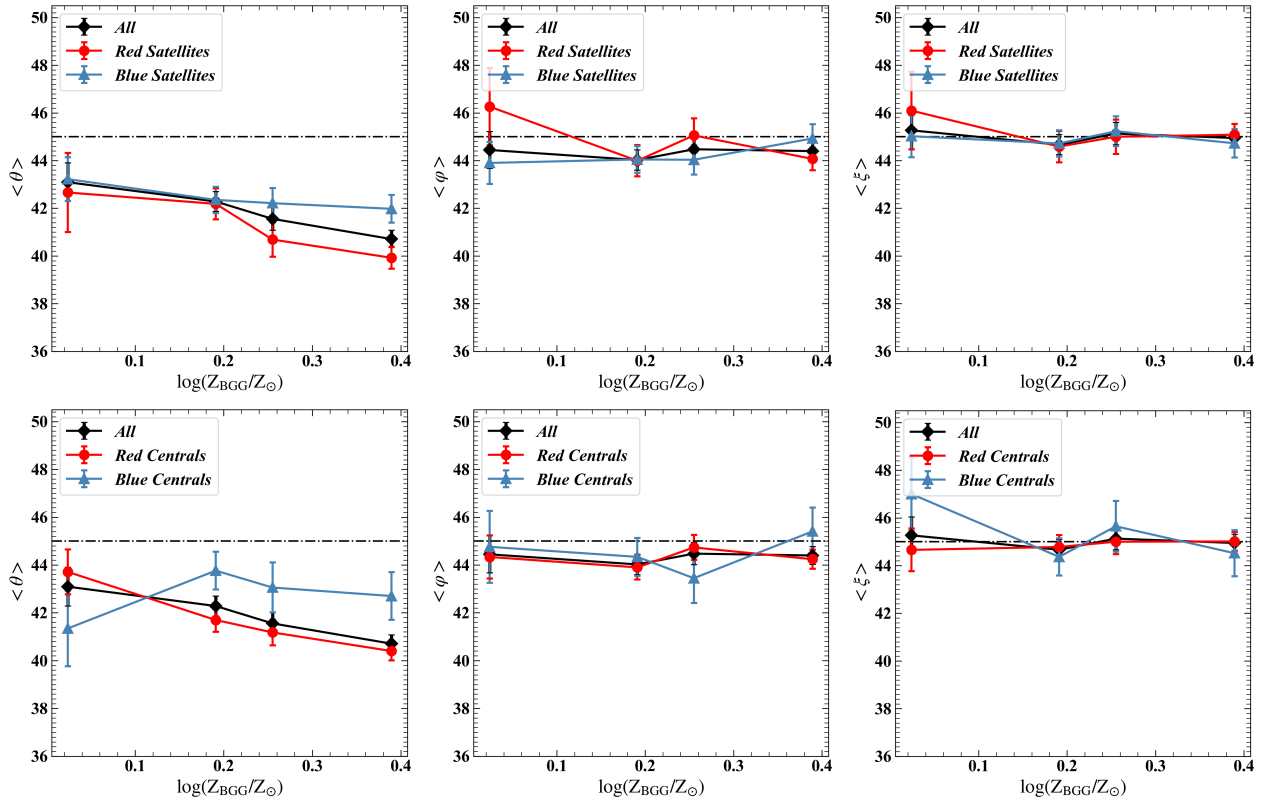

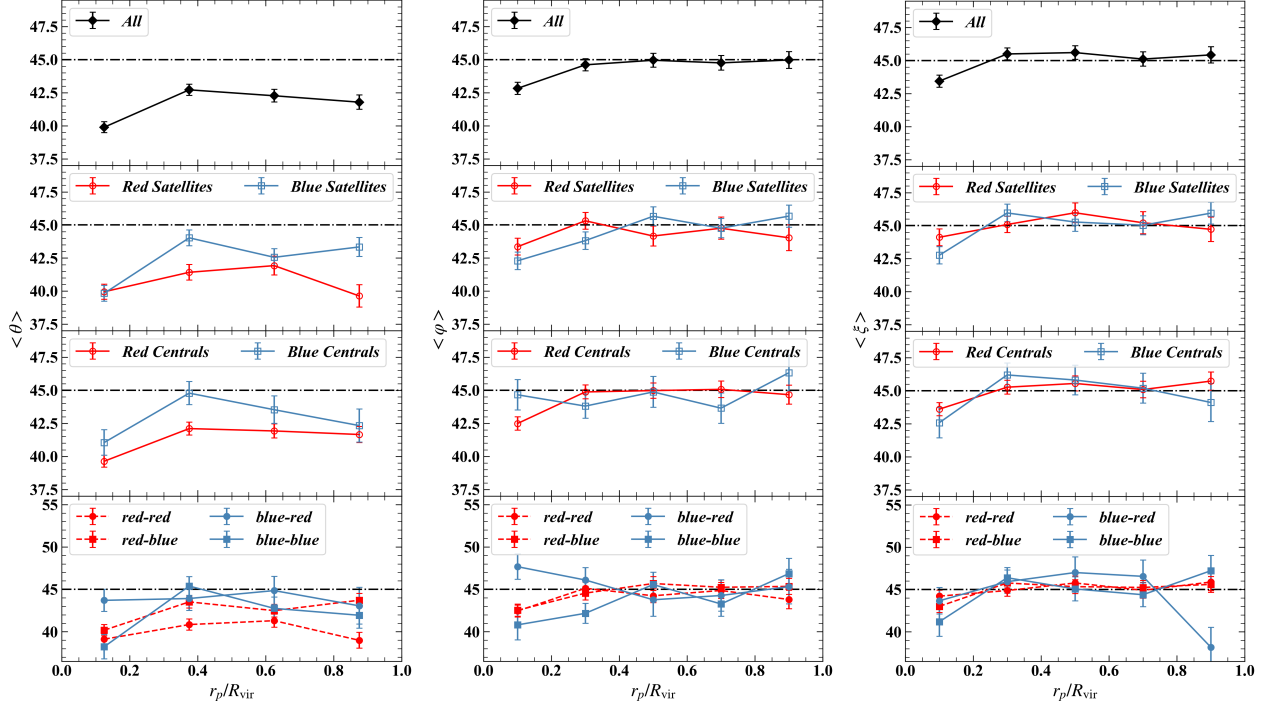

Figure 8. Same as Figure 5, but for the dependence on BGG metallicity.

This underscores the importance of surface brightness thresh- olds in analyzing alignment signals and morphology within

**Figure 9.** Average alignment angles for all satellites and the four color subsamples (indicated in the legends of each panel), as functions of projected distances from the satellites to the center of host halo, normalized by the halo virial radius. The panels in each column, from left to right, correspond to satellite-central alignment, radial alignment, and direct alignment, respectively.

**Figure 10.** The variation of BGG major axes with different surface brightness thresholds. The black solid lines are for all BGGs, while the blue, green and red lines are for three mass subsamples, as indicated in the upper-left corner of each panel. Here,  $\alpha$  represents for the position angle of BGG major axis and the benchmark is set to position angle of BGG major axis at a surface brightness threshold of  $\mu_r = 28.5$  mag arcsec $^{-2}$ . The left and right panels shows results for halo and BGG mass, respectively.

galaxy clusters. We suggest conducting deep image surveys to reveal the radial and direct alignment phenomena.

#### 4. CONCLUSIONS AND DISCUSSION

In this paper, the TNG100-1 simulations have been utilized to explore three types of galaxy alignment and how they relate to galaxy or halo properties by applying mock observation techniques.

First of all, the simulation predictions accurately replicate the satellite-central and radial alignment effects for the

**Table 2.**  $\langle\theta\rangle, \langle\varphi\rangle, \langle\xi\rangle$  for mock samples with different surface brightness thresholds

SB thresholds	$\langle\theta\rangle$	$\langle\varphi\rangle$	$\langle\xi\rangle$	number of pairs
[mag arcsec <sup>2</sup> ]	[degree]	[degree]	[degree]	
24.5	41.6	44.9	45.5	8371
25.0	41.6	44.3	44.9	12987
25.5	41.2	44.0	44.6	18041
26.0	41.1	44.2	44.5	23518
26.5	40.8	44.0	44.6	29511
27.0	40.6	43.9	44.7	36562
27.5	40.5	43.7	44.6	43760
28.0	40.7	43.2	44.6	51599
28.5	40.7	42.7	44.6	59728

entire mock sample (i.e., all BGG-satellite pairs), aligning well with observational findings (Yang et al. 2006; Rodriguez et al. 2022). However, no significant signal is detected for direct alignment. Specifically, satellite galaxies tend to align along the major axis of their host BGG and orient their major axes towards the center of their central galaxy. Nevertheless, there is minimal correlation between the orientation of satellite galaxies and the orientation of their host BGG.

Our study reveals that most predictions on galaxy alignment and its dependence on halo or galaxy properties are in line with previous research, with some slight discrepancies. The main findings on satellite-central alignment, radial alignment, and direct alignment will be summarized and discussed separately.

For satellite-central alignment, predictions using single-color and double-color subsamples demonstrate alignment strengths and color-dependent trends in good agreement with observational results. Our results compellingly demonstrate that the strength of satellite-central alignment increases for single color subsamples in the following order: ‘Blue Centrals’, ‘Blue Satellites’, ‘Red Centrals’, and ‘Red Satellites’. Consequently, we argue that this study is the first to accurately predict the trend of color dependence in satellite-central alignment. It is noteworthy that Kang et al. (2007) used a semi-analytical model to predict the same color dependence and found a different order: ‘Blue Satellites’, ‘Red Centrals’, ‘Blue Centrals’, and ‘Red Satellites’. They also identified an alternative order: ‘Blue Satellites’, ‘Blue Centrals’, ‘Red Centrals’, and ‘Red Satellites’ when considering the spin axes as the major axes of central galaxies. None of these previous predictions yielded the correct color dependence. Nevertheless, it should be noted that in our prediction there are still exceptions where the ‘Blue Centrals’ and blue-blue subsamples exhibit significantly pronounced alignment

signals (Yang et al. 2006; Rodriguez et al. 2022). The successful fit of predictions from the blue-red subsample with observational results suggests that the excessive satellite-central alignment observed in the ‘Blue Centrals’ subsample can be attributed to the abnormal behavior of the blue-blue subsample. Additionally, the exceptional alignment signals on small scales indicate that the discrepancy is primarily due to the overly strong anisotropy distribution of blue satellites around blue central galaxies in the simulations. This suggests a potential issue with the color assignments for blue satellites in the simulations. Furthermore, on average, there is a positive correlation between alignment strengths and halo mass, which aligns well with the observed dependence (Yang et al. 2006) and previous predictions made using Gadget-2 simulations (Dong et al. 2014; Tang et al. 2020). Predictions were made for the alignment strengths of halos based on BGG mass, age, and metallicity, revealing positive correlations with these properties, mirroring the mass-dependence trends. The metallicity-dependence results resemble predictions for satellites (Dong et al. 2014) but lack observational validation. Furthermore, alignment strengths across all color subsamples exhibited radial dependence or proximity effects. The strength of satellite-central alignment signals is significantly influenced by the proximity of satellite galaxies to the central galaxy, with closer satellites yielding stronger alignment signals. These findings align well with both observational studies (Yang et al. 2006; Faltenbacher et al. 2007) and previous predictions (Dong et al. 2014) regarding radial dependence. The dependencies on halo/BGG mass, BGG age, and metallicity can be understood within the framework of cosmic structure and galaxy formation. On one hand, it is widely recognized that central galaxies in more massive halos tend to be more massive themselves, possess older average stellar ages, and exhibit higher average stellar metallicities. However, these relationships are complex, nonlinear, and have significant scatter. On the other hand, studies have shown that satellite galaxies often follow an asymmetric infall pattern and are preferentially accreted along the major axis of host halos with higher mass (e.g., Wang et al. 2005; Libeskind et al. 2015; Kubik et al. 2017; Morinaga & Ishiyama 2020). This anisotropic distribution of satellite galaxies leads to a significant satellite-central alignment. Consequently, it is reasonable to expect positive correlations between satellite-central alignment strength and halo mass, BGG mass, BGG age, and BGG metallicity. Nevertheless, it has been observed that the predicted alignment strengths for the blue subsample exhibit significant variability based on BGG properties. This variability can be attributed to the complexity of blue galaxies, as they are challenging to characterize without additional information such as merger history, and dynamical stage. Further investigations are needed.

In terms of radial alignment, it has been observed that there is almost no color dependence within single-color subsamples, although weak but noticeable signals have been detected. On the other hand, when considering double-color subsamples, significant radial alignment signals are present in the red-red and blue-blue subsamples, while the red-blue and blue-red subsamples show minimal radial alignment. These results can be explained by the “galactic conformity” phenomenon and the influence of tidal stripping on galaxy alignment. When analyzing all color subsamples, the trends in dependence on halo mass or BGG mass appear to be similar. Specifically, the radial alignment signal tends to be stronger at the lower mass end. However, it is found that the relationship between radial alignment and BGG age and metallicity is weak and complex for the entire sample and all subsamples, with significant scatter due to small number statistics. Furthermore, a clear proximity effect is observed, as the predicted alignment signals from the entire mock sample and subsamples for central galaxies are significant at scales where the projected distance is less than 0.2 times the virial radius. There have been found discrepancies between the predicted dependence of proximity effect on satellite colors and observational results (Faltenbacher et al. 2007). However, it is important to note that the definition of BGG colors in this study may differ from that used in the study by Faltenbacher et al. (2007). Further investigation and refinement of methodologies may be necessary to reconcile these differences and enhance our understanding of radial alignment phenomena in galaxy systems.

For direct alignment, no signals were detected in the entire mock sample or in any of the single-color and double-color subsamples. There was also no apparent dependence on halo/BGG mass, BGG age, or metallicity. However, there have been found significant alignment on scales of  $r_p \lesssim 0.2R_{vir}$ , generally consistent with observations (Faltenbacher et al. 2007).

Moreover, it is also revealed that galaxy orientations are affected by surface brightness contours, emphasizing the importance of adopting consistent thresholds for a fair comparison with observations. Galaxy alignment, essential for understanding galaxy properties, depends on factors such as surface brightness thresholds, PSF effects, and redshift distribution, etc. The importance of selection effects in mock observations using simulations, as emphasized in Tang et al. (2021), stresses the necessity of accounting for these factors to ensure proper and accurate comparisons.

The scenario of galaxy formation within the context of cosmic structure formation provides a comprehensive understanding of the various alignment signals observed in satellite galaxies. The satellite-central alignment, driven by the large-scale structure of the universe, sets the stage for the subsequent radial alignment phenomenon influenced by tidal

forces (e.g., Ciotti & Dutta 1994; Usami & Fujimoto 1997). As satellite galaxies move towards the center of the host dark matter halo along the principal axis of the central galaxy, they experience increasing tidal forces that gradually align their shapes and orientations towards the central galaxy. This process leads to a stronger radial alignment signal in satellite galaxies closer to the center of the dark matter halo, reflecting the intensity of the tidal forces exerted on them. In contrast, the direct alignment signals, which represent the difference between satellite-central alignment and radial alignment angles, are relatively weak and without clear theoretical prediction (c.f., Faltenbacher et al. 2007). This suggests that the direct alignment may be a more subtle or complex alignment mechanism compared to the satellite-central and radial alignments. Overall, the combined effects of satellite-central alignment, radial alignment due to tidal forces, and the potential presence of direct alignment paint a nuanced picture of how satellite galaxies align with their host dark matter halos and central galaxies during the cosmic evolution of structures.

In addition, the comparison between the alignment signals obtained from mock observations and those derived from stellar substructures using the SUBFIND algorithm reveals interesting insights into the accuracy and reliability of different methods in studying satellite galaxy alignments. While the mock observational galaxies generated through galaxy reconstruction techniques offer a closer resemblance to the observed satellite distributions and orientations, indicating a higher level of accuracy in capturing the alignment signals, it is essential to note that the signals obtained from stellar substructures are still remarkably significant for all three types of alignment - satellite-central alignment, radial alignment, and direct alignment. This suggests that while the mock observational galaxies may provide a more realistic representation of the observed satellite galaxy alignments, the signals derived from stellar substructures using algorithms like SUBFIND still hold considerable value in understanding the alignment phenomena in cosmic structures. The combination of both approaches can offer a more comprehensive and robust analysis of satellite galaxy alignments, helping us gain deeper insights into the complex interplay between galaxies, dark matter halos, and the large-scale structure of the universe. It is suggested to take sufficiently deep galaxy images to find the outer faint ingredients and recover the prominent alignment signals derived from substructures (see, e.g., Johnston et al. 2001, for estimation and discussions).

In summary, while the explanations for satellite-central alignment are well-understood and dependent on certain properties, the reasons behind radial and direct alignment are more complex and not fully elucidated due to various factors influencing the alignment patterns. Our analysis underscores the importance of galaxy properties and positions in

influencing satellite alignment signals. These results offer valuable contributions to unraveling the mechanisms governing galaxy alignment and shed light on the intricate interplay between galaxy properties and their distribution within dark matter halos. By delving deeper into these alignment phenomena, we can enhance our understanding of the intricate processes shaping the cosmic web and the distribution of galaxies within it. Furthermore, precise quantification of galaxy intrinsic alignment is crucial for mitigating its impact on weak lensing analyses (e.g., Heymans et al. 2004; Kirk et al. 2015; van Uitert et al. 2017; Zhang et al. 2022; Zhou et al. 2023). Given the challenges in simulating galaxy formation due to the complexity and costs involved, there is a need to further uncover the detailed physical mechanisms underlying satellite-central alignment. Addressing the discrepancies identified in this study will require advanced simulations and innovative methodologies in the future. By ad-

vancing our understanding of satellite-central alignment and developing improved simulation techniques, we can refine our models and enhance the accuracy of weak lensing analyses. This will ultimately contribute to more reliable interpretations of observational data and deepen our knowledge of the complex interplay between galaxies and dark matter halos in the universe.
